The greater damage caused by soil incorporation of herbicides over surface application appears to be related to the amount of herbicide absorbed. Kozlowski and Kuntz[12] showed that very young pine seedlings readily absorbed soil-incorporated triazine herbicides and were killed, whereas surface-applied herbicides which were not easily absorbed by plant roots were less toxic. When various triazine herbicides were applied to the soil surface and leached, most of the herbicide remained in the surface inch of soil regardless of whether 2, 4 or 8 surface inches of water were used in leaching. Old seedlings escaped injury from surface-applied triazines largely because their absorbing roots were sufficiently deep to avoid taking up the surface-concentrated herbicide. Old seedlings were readily killed, however, when small amounts of triazine herbicides were incorporated in the zone of absorbing roots. Such observations are reinforced by those of Freeman[13], who noted that pine seedlings were killed by simazine within 5 weeks of germination. In contrast, oak seedlings were not damaged largely because of the rapid movement of the absorbing zone of their roots to levels below that of the herbicide concentration.

EFFECTS OF ALCOHOL CONSUMPTION ON THE ACTIVITY OF LIVER ENZYMES IN *C57BL/Crgl* MICE

By Dr. KURT SCHLESINGER
Department of Psychology, University of North Carolina, Chapel Hill
Dr. EDWARD L. BENNETT and MARIE HEBERT
Laboratory of Chemical Biodynamics, University of California, Berkeley
AND
Prof. GERALD E. McCLEARN
Department of Psychology, University of California, Berkeley

INCREASED alcohol dehydrogenase (ADH) activity has been reported in mice, rats and men following the consumption of alcohol for prolonged periods[1]. These previous reports indicate that consumption of alcohol increases the activity of enzymes involved in its metabolism. In the present study the generality of the effect of alcohol on activity of alcohol dehydrogenase, xanthine oxidase (XO) and hexokinase (Hk) in liver has been investigated. Hk is not directly involved in alcohol metabolism and the importance of XO in the *in vivo* metabolism of alcohol has not been established. In addition, the influence of alcohol ingestion on liver protein content was investigated.

Male *C57BL/Crgl* mice, obtained from the Cancer Research Genetics Laboratory, University of California, Berkeley, were used for the experiments[2]. All animals were 60 ± 3 days old at the beginning of the experiments.

Fifty-eight mice were used in three experiments; twenty animals were used in the first experiment, twenty in the second and eighteen in the third. Animals were randomly assigned, and in equal numbers, to the experimental and control condition in each experiment. Experimental animals were given a 10 per cent solution of ethyl alcohol as their sole drinking source for 90–104 days; control animals were maintained on tap water for an equivalent period. All animals had free access to standard laboratory diet.

The mice were weighed to the nearest 0·1 g before being killed by decapitation. The liver was immediately removed and weighed to the nearest mg. In the second experiment, one lobe was dissected and separately weighed. This lobe was dried to constant weight (± 1 mg) *in vacuo* using a dry ice-isopropyl alcohol trap.

The fresh livers were homogenized with a 'Teflon'-glass homogenizer in distilled water at 0° and diluted to a final concentration of 50 mg/ml. A portion of the homogenate was centrifuged at 0° for 30 min at 3,000 r.p.m. (International model *PR*-1 centrifuge). The supernatant, excluding the lipid layer, was removed and used for alcohol dehydrogenase (ADH) assays and for some of the protein analyses. Uncentrifuged homogenates were used for XO and Hk assays and for some of the protein analyses. All enzyme assays were carried out in duplicate; duplicate assays agreed within 5 per cent.

ADH assays were performed as follows: 3·0 ml. of a glycine-semicarbazide buffer[3], 0·20 ml. of 0·015 M nicotinamide-adenine dinucleotide (NAD), and 0·050 ml. of a 0·35 M ethanol solution were mixed in 10 mm light path spectrophotometer cells. After pre-warming the incubation mixture at 37° for 10 min, 50 µl. of the supernatant from the liver homogenate were added and mixed. The rate of reduction of NAD was measured by the increase in absorption at 340 mµ. A Beckman spectrophotometer equipped with a Gilford model 210 automatic cuvette positioner, a model 220 optical density converter, a recorder and a 37° cell compartment were used. The absorbancies of four samples were sequentially recorded in automatic rotation at 30-sec intervals for 10–12 min. This procedure has already been described in greater detail[4]. In the absence of added ethanol, no change in absorbance was noted during a 10 min incubation.

Hk activity was determined by a procedure modified from that described for brain[5]. Three ml. of a solution containing 0·13 M glycylglycine, 0·02 M magnesium chloride, 0·001 M nicotinamide-adenine dinucleotide phosphate (NADP), 0·025 M glucose and 0·01 M adenosine triphosphate (ATP) (final *p*H adjusted to 8·0) and 0·06 ml. of a glucose-6-phosphate dehydrogenase solution (50 µg/ml.) were pre-warmed to 37°. The uncentrifuged liver homogenate (0·075 ml.) was then added and the rate of reduction of NADP was measured by the increase in absorption at 340 mµ using a Beckman *DU* spectrophotometer and auxiliary recording equipment.

XO activity was determined by the method described by Udenfriend[6]. 2-Amino-4-hydroxypteridine is readily oxidized by XO to isoxanthopteridine[7]. The activity of the enzyme may be determined spectrofluorometrically since the fluorescence of the substrate, 2-amino-4-hydroxypteridine, is quenched in phosphate buffer, while that of the product is not. To determine XO activity 10-ml. aliquots of 0·1 M sodium phosphate buffer containing 4×10^{-6} M 2-amino-4-hydroxypteridine were pipetted into 50 ml. Erlenmeyer flasks, which were then placed into a metabolic shaker and warmed to 30°. Afterwards, 0·25 ml. of the uncentrifuged homogenate was added and the mixture was incubated in the shaker-water bath for 60 min. A 2-ml. portion was withdrawn and analysed in an Aminco–Bowman spectrophotofluorometer. The activating wave-length was 250 mµ and the analysing wave-length was 420 mµ. The machine was set at 'zero' before each determination and the value of a blank (containing everything in the sample except the enzyme) read. Values of the blank did not change with time. After all determinations had been made 10 µl. of milk XO were added to each flask to oxidize completely the 2-amino-4-hydroxypteridine. The fluorescence of this sample was then determined after 30 min on a 2 ml. portion. These final readings did not differ from sample to sample by more than 2 per cent. Under these conditions of measurement, fluorescence was shown to be a linear function of the amount of substrate oxidized.

The protein content of the livers was determined in triplicate with the Folin phenol reagent[8]. The original liver homogenate was diluted with water to 2 mg/ml. Aliquots containing 1 mg of wet tissue were mixed with 5 ml. of alkaline copper sulphate reagent *C* in 12-ml. centrifuge tubes. After 10 min, 0·50 ml. of dilute Folin–Ciocalteau reagent was added and rapidly mixed. The optical density at 750 mµ was determined in a Beckman *DU* spectrophotometer after 60 min. Suitable aliquots of freshly diluted crystalline bovine albumin solutions (Armour) were run as standards. All results were referred to this standard (mg protein = mg nitrogen × 6·25). Protein results were expressed as a percentage of the wet

tissue weight. In the second experiment, protein determination was made both on the liver homogenates that had been centrifuged and on those that had not.

Liver-weight and body-weight were not significantly different in control and experimental animals. In one of the three experiments, the ratio of liver-weight to body-weight was significantly greater in the experimental animals ($P < 0.05$), but this finding was not replicated in the other experiments.

Dry-weight determination of a liver lobe of the animals used in the second experiment indicates that no differences in the ratio of dry weight/wet weight existed between experimental and control animals. The percentage dry-weight of the liver lobe was 33 per cent in both the experimental and the control animals (range, 32–34 per cent in both experimental and control groups).

Prolonged alcohol consumption significantly increased ADH activity in liver by about 20 per cent (Table 1). These differences were statistically significant and of the same order of magnitude regardless of whether ADH activity was expressed as μmoles/min/entire liver, μmoles/min/g liver or μmoles/min/g liver/g mouse. Since all methods of expressing the data gave approximately the same results, only those for μmoles/min/g liver are given in Table 1.

Table 1. PERCENTAGE OF PROTEIN AND ADH ACTIVITY IN EXPERIMENTAL AND CONTROL *C57BL/Crgl* MICE

Exp. No.	Condition	N	Protein in liver* (per cent) $\bar{X}$	S.D.	ADH activity (μmoles/min/g liver) $\bar{X}$	S.D.
(1)	Experimental (alcohol)	10	18·17	0·18	4·41	0·66
	Control (water)	10	16·55	1·13	3·62	0·67
	Percentage difference		12		18	
	P value		< 0·01		< 0·02	
(2)	Experimental (alcohol)	10	18·23	1·08	6·56	0·32
	Control (water)	10	16·13	1·66	5·25	0·39
	Percentage difference		12		20	
	P value		< 0·01		< 0·01	

* The percentage of liver protein is based on the analyses of the uncentrifuged homogenates.

Liver Hk activity was not significantly different in control and experimental animals (Table 2).

XO activity/g liver was significantly decreased in experimental animals, by 43 per cent in the second experiment and by 48 per cent in the third (Table 2).

Liver protein (expressed as a percentage of the liver wet weight) was significantly increased in experimental animals by 12 per cent in the first experiment and 12 per cent in the second. These differences were found whether the protein analyses were made on the centrifuged or uncentrifuged liver homogenates. For this reason only the results obtained with the uncentrifuged liver homogenate are summarized in Table 1.

The differences in ADH activity in liver between experimental and control mice, when enzyme activity is expressed per unit protein, were 6 per cent in the first experiment and 9 per cent in the second. These differences, although quite small in magnitude, are statistically significant ($P < 0.01$ and $P < 0.01$ for Experiments 1 and 2 respectively).

The finding that ADH activity in liver is increased following the consumption of alcohol is in good agreement with the results reported by several other investigators. McClearn, Bennett, Hebert, Kakihana and Schlesinger[1] have shown increased ADH activity in *C57BL/Crgl* and *DBA/2Crgl* mice maintained on 10 per cent alcohol for 2–4 weeks. Kakihana, Schlesinger and McClearn[1] were able to demonstrate increased ADH activity in 12-week-old *BALB/cCrgl* mice, but not in 6- or 9-week-old mice, which had been maintained on alcohol for a 2-week period; the younger *BALB/cCrgl* mice had high endogenous ADH activity. Figueoroa and Klotz[1] and Dejani, Danielski and Orten[1] also reported increased ADH activity in the rat following alcohol ingestion; Dejani *et al.* reported increased acetaldehyde dehydrogenase activity in rats following ingestion of alcohol.

Table 2. EFFECTS OF ALCOHOL CONSUMPTION ON XANTHINE OXIDASE AND HEXOKINASE ACTIVITY IN *C57BL/Crgl* MICE

Exp. No.	Condition	N	Xanthine oxidase activity (μmoles/h/g liver) $\bar{X}$	S.D.	Hexokinase activity (μmoles/min/g liver) $\bar{X}$	S.D.
(2)	Experimental (alcohol)	10	0·96	0·12	——	——
	Control (water)	10	1·42	0·19	——	——
	Percentage difference		43			
	P value		< 0·001			
(3)	Experimental (alcohol)	7	0·48	0·15	3·08	0·025
	Control (water)	7	0·93	0·48	3·22	0·14
	Percentage difference		48		4	
	P value		< 0·01		*N.S.*	

All these reports have focused on the activity of only one enzyme. The increased liver protein content observed in experimental animals was unexpected and complicates the interpretation of the observed increase in ADH activity. This difference in liver protein content could, for example, mean that the increased ADH activity is merely a secondary reflexion of the total increase in liver protein. If the argument is to be maintained that ingestion of alcohol increases activity of the enzymes involved in its oxidation, then it is necessary to demonstrate that enzymes not directly involved in alcohol metabolism are not affected by ingestion of the substrate.

Two other enzymes were measured in these experiments. Hk was not directly involved in alcohol metabolism and the importance of XO in the *in vivo* metabolism of alcohol was not established. The activity of XO decreased with ingestion of alcohol and the activity of Hk was not affected by this treatment, while the activity of ADH increased. These findings suggest that only those enzymes directly involved in the metabolism of alcohol are affected by ingestion of the substrate.

The fact that liver-weight and body-weight were not changed by the ingestion of alcohol was also surprising. Liver water content was also not changed. Because liver protein content was increased by ingestion of alcohol and because the liver weight and the water content of the liver remained unchanged, some liver constituent(s) must be decreased. What these constituents are remains to be determined.

The results of the ADH analyses in the two experiments are not in very good agreement in terms of absolute magnitudes of enzyme activity. Such day-to-day discrepancies are probably due to the fact that the various reagents are made up fresh for each experiment. Because comparisons are made between experimental and control animals within a given experiment, however, these discrepancies are not too serious. It should be noted that the relative differences between experimental and control mice are in good agreement for all experiments. The differences in absolute oxidation rate in the XO assays are attributed to difficulties in completely dissolving the substrate. Again, comparisons were made within experiments, and the relative differences between experimental and control animals were in good agreement for all experiments.

This research was aided by fellowship *F1 MH-16*, 102-02 from the National Institutes of Health. It was also aided by the U.S. Atomic Energy Commission.

LETTERS TO THE EDITOR

ASTROPHYSICS

Improved Resolution X-ray Photographs of the Sun

A FOURTH successful firing of the new Sun-pointed *Skylark* research rocket[1] took place at 0520 G.M.T. on October 20, 1965, at Woomera, Australia. The flight was designated *SL* 306 and on board were instruments prepared by Culham Laboratory and University of Leicester Groups for study of the short-wave-length emission of the Sun. This note presents a number of new X-ray photographs of the Sun obtained by the Leicester Group, using a camera array similar to that successfully utilized in the three earlier *Skylark* flights[2–4]. Two significant changes in the present camera were the inclusion for the first time of a Fresnel zone plate[5] unit and the improvement of the geometrical resolution on one pin-hole camera unit to 1 arc min. The latter improvement was encouraged by the increased exposures available from the predicted trajectory of the new, more powerful, *Raven* 6*A* rocket motor. The zone plate was flown primarily to test its rocket-worthiness prior to use in 1966 in the first Mark II stabilized *Skylark*, when an attempt will be made to obtain photographs of the Sun in monochromatic radiation with resolution of 10–20 arc sec. In the present flight the zone plate camera was focused for the Lyman-α line of *C* VI, recently[6] found to be one of the strongest short-wave-length emission lines in the solar spectrum. Full details of the camera array are given in Table 1.

Table 1. DETAILS OF THE CAMERA UNITS (NOMINAL VALUES)

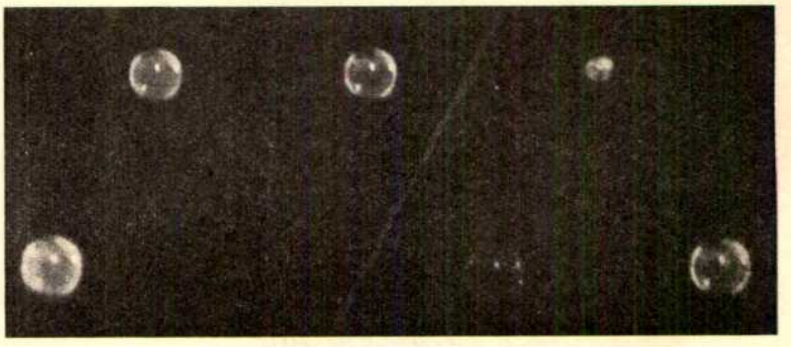
Unit	Filter (μ)	Wave-length band 10% (Å)	Focal length (in.)	Pin-hole or zone plate diameter (10^{-3} in.)	Resolution (arc min)
A	0·3 Aluminium	< 40	7·4	5	2
B	1·0 Polypropylene + 0·15 aluminium	< 32 and 44–48	7·4	5	2
C	0·3 Aluminium	< 40	3·4	1·4 (inner zone) 8·7 (outer zone)	0·1*
D	0·3 Aluminium	< 40	8·4	10	4
E	1·5 Polypropylene + 0·1 aluminium	< 32 and 44–48	8·4	2·5	1
F	1·5 Aluminium	< 24	8·4	10	2
G	1·5 Polypropylene + 0·1 aluminium	< 32 and 44–48	8·4	10	2

* This resolution would only be realized for monochromatic radiation of 33·7 Å and a finer grain emulsion than that used in this flight.

The flight performance of *SL* 306 was excellent, reaching an apogee of 213 km and providing effective exposure of the cameras during the controlled phase of almost 5 min. Further, analysis of the initial flight records has shown the pointing control was the best so far achieved. Throughout the whole pointed phase, roll drift and lateral pointing noise were too small to be measured on the low-speed telemetry records so far available. It seems likely that the lateral noise figure of 20 arc sec obtained on this control unit during tests at Elliott Automation may have been achieved in flight, owing to the use for the first time of a higher gain error-signal amplifier. The major pointing movement appears to have been a slow lateral drift of the instrument payload relative to the control bay, due to heating of the rocket during the launch phase. A slight elongation of the X-ray images reported here supports such a drift of about 2 arc min parallel to the north–south axis of the Sun.

The condition of the Sun[7] on October 20 was 'fairly quiet', only three small chromospheric plages being evident on the disk, at 20° N.–5° W., 20° N.–65° W. and 30° S.–30° E. Of these, the plage near the centre of the disk had brightened considerably on the day prior to the flight. The only other feature evident in the *H*-alpha photographs are a number of dark filaments in the north-west quadrant, being remnants of old active regions. The provisional sunspot number on the day was 17 and the 10·7 cm radio noise index was 73.

X-ray images *A*–*G* are reproduced in Fig. 1, and enlargements of *B*, *C* and *E* are shown in Fig. 2. The following observations may be made from initial examination of the negatives.



(*a*) X-ray enhancements are seen associated with all three chromospheric plages. Of particular note is the apparent size of the two low-latitude regions from image *E*. The measured size is 3 × 1 arc min and, after allowance for camera resolution of 1 arc min and the probable north–south thermal drift, it is clear that each X-ray source is even smaller than the 1 arc min estimated for earlier photographs[8].

(*b*) The very small motion of the pointing control parallel to the solar equator provides a true measure of the limb brightening which can be seen to have greater extent in an east–west direction than the plage-associated sources. Polar darkening is again clearly seen.

(*c*) A general increase in X-ray emission is found in the north-west quadrant of the disk, and this is particularly noticeable on the zone plate image. This emission probably indicates higher coronal densities in this area, possibly associated with the old activity seen as filaments in the chromosphere.

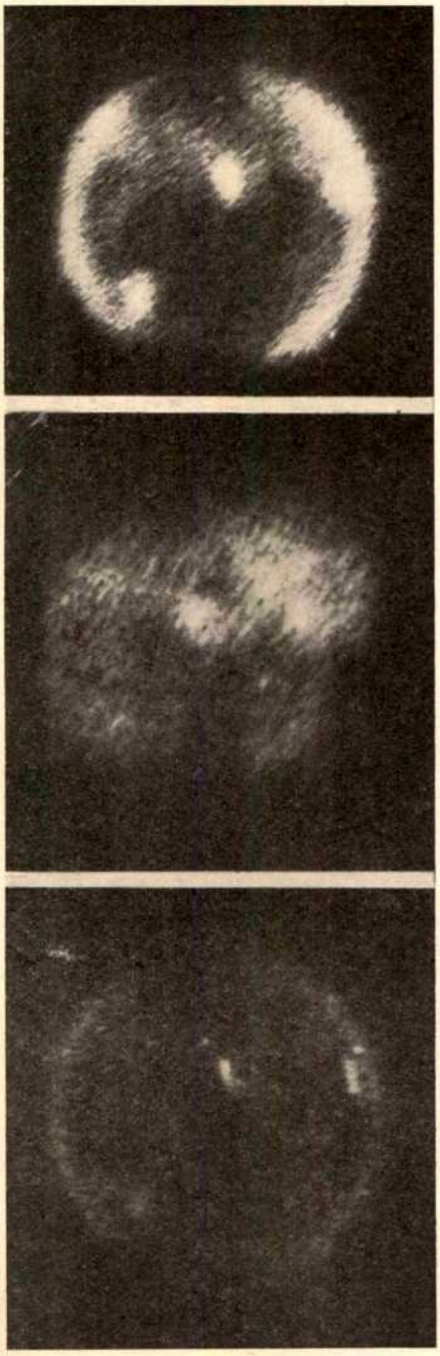
(*d*) Dark regions are clearly seen on the disk for the first time (compare images *B* and *G*) and it is notable that a dark region, probably therefore of lower density, is seen either side of the central plage, which was in process of rapid enhancement. A similar association of a dark patch with a newly forming bright X-ray region was seen on flight *SL* 301, but on that occasion the poorer image resolution made this association less distinct.

(*e*) Of particular interest is the higher disk emission on image *A* compared with image *B*, particularly as the transmission of filter *A* exceeds filter *B* only below 43 Å. It seems possible that this observation may be due to the greater sensitivity of camera *A* for the *O* VII lines at

A *B* *C*

D *E* *F* *G*

Fig. 1. Images *A*–*G*



21·5 Å, reported earlier[9] to be very strong in the solar spectrum. The lower coronal temperature outside the active regions, found in analysis of the earlier photographs[8], would support the occurrence of abundant *O* VII, requiring the relatively low ionization energy of 170 eV, in the general corona.

(*f*) Image *C*, from the zone plate camera, is noticeably less distinct than the pin-hole camera images. This camera was set for prime focus at 33·7 Å, the Lyman-α line of *C* VI, but the thin aluminium filter also transmitted shorter wave-lengths. The two low-latitude plages appear relatively sharp, probably due to the abundance of *C* VI in the active corona, this being a relatively high-energy state, of ionization energy 380 eV. It seems likely that much of the out-of-focus emission from the disk, particularly evident in the north-west quadrant, may be again due to the 21·5 Å lines of *O* VII. Post-flight checks have shown that the zone plate was set in error for focus at 40 Å. This will have contributed to the blurring of the image but does not affect the conclusions drawn.

We thank the staff of the Royal Aircraft Establishment, Farnborough, and of Elliott Automation for their respective parts in successful stabilized *Skylark* vehicle, and the staff of the Weapons Research Establishment, Salisbury, for the launch. The technical assistance of colleagues in the Department of Physics in preparation of the cameras and, in particular, of John Larrad, who conducted the flight trial in Australia, are gratefully acknowledged. For the preparation of zone plates for this and future payloads and for laboratory study, we thank Prof. Möllenstedt of the University of Tübingen, Germany.

COSMOLOGY

A Cosmological Model

(I) It is familiar that the Einstein equations for the density and pressure in a uniform universe:

$$8\pi G\rho = \frac{3}{R^2}(kc^2 + R'^2) - \Lambda \qquad (1)$$

$$8\pi G\frac{p}{c^2} = -2\frac{R''}{R} - \frac{R'^2}{R^2} - \frac{kc^2}{R^2} + \Lambda \qquad (2)$$

do not suffice to specify the model since there are two equations and three unknown functions, ρ, p and R. A very common assumption is $p = 0$, but models involving both positive and negative values of p have also been proposed. McCrea[1] pointed out that there is no objection in principle to negative pressure and that the steady-state universe can be interpreted in this way.

The model discussed here belongs to this negative pressure class but with a different 'equation of state'. Its particular interest is that it seems to provide a possibility of linking the cosmological parameters with familiar laboratory constants.

(II) Let us first make:

Hypothesis A :

$$p = -\frac{2}{3}\rho c^2 \qquad (3)$$

If this is inserted in the equation:

$$\frac{d}{dt}(\rho R^3) + \frac{p}{c^2}\frac{dR^3}{dt} = 0 \qquad (4)$$

which is obtained by eliminating Λ between (1) and (2), there results:

$$\frac{d}{dt}(\rho R) = 0$$

so that:

$$\rho R = L \text{ (a constant)} \qquad (5)$$

Following McVittie[2] we introduce the density parameter, σ_0, and the pressure parameter, ε_0, at the instant t_0, defined by:

$$\sigma_0 = \frac{4}{3}\pi G\rho_0 T_0^2,\ \varepsilon_0 = \frac{p_0}{\rho_0 c^2},\ T_0 = \frac{R_0}{R'_0} \qquad (6)$$

and also the acceleration factor $q_0 = -R''_0R_0/R'^2_0$. Thus equation (3) gives $\varepsilon_0 = -2/3$ and the Einstein equations can be written:

$$\Lambda = -3(q_0 + \sigma_0)T_0^{-2} \qquad (7)$$

$$k\left(\frac{cT_0}{R_0}\right)^2 = -(q_0 + 1 - \sigma_0) \qquad (8)$$

In these, q_0, σ_0 and T_0 can be regarded as having numerical values derived from observation. The equation corresponding to equation (7) in the zero-pressure model is:

$$\Lambda = -3(q_0 - \sigma_0)T_0^{-2} \qquad (7)'$$

Comparison of equations (7) and (7)′ brings out an important difference. In equation (7)′ it is possible for Λ to be zero or positive for positive values of q_0 and σ_0, and in fact it is widely assumed that $\Lambda = 0$. With equation (7) this is not possible. If q_0 and σ_0 are positive then Λ is certainly negative.

If, as seems very likely, $q_0 + 1 > \sigma_0$, the left-hand side of equation (8) must be negative so that $k = -1$. Thus:

$$\left(\frac{cT_0}{R_0}\right)^2 = q_0 + 1 - \sigma_0 \qquad (9)$$

and this, combined with equations (5) and (6), gives:

$$\frac{\sigma_0}{\sqrt{(q_0 + 1 - \sigma_0)}} = \frac{4}{3}\pi\frac{G}{c}LT_0 \qquad (10)$$

Reverting to equation (1), this can now be written:

$$R'^2 = c^2 + \frac{8\pi}{3}GLR - \frac{1}{3}(-\Lambda)R^2 \qquad (11)$$

which represents an oscillating hyperbolic universe.

If we introduce homogeneous variables $Y = R/R_0$, $X = t/T_0$, then equation (11) can be written:

$$\left(\frac{dY}{dX}\right)^2 = q_0 + 1 - \sigma_0 + 2\sigma_0 Y - (q_0 + \sigma_0)Y^2 \equiv \varphi(Y) \qquad (12)$$

and the age of this universe is AT_0, where:

$$A = \int_0^1 \{\varphi(Y)\}^{-\frac{1}{2}}\,dY = \frac{1}{\sqrt{(q_0 + \sigma_0)}}\left\{\sin^{-1}\frac{q_0}{\sqrt{(q_0^2 + q_0 + \sigma_0)}} + \sin^{-1}\frac{\sigma_0}{\sqrt{(q_0^2 + q_0 + \sigma_0)}}\right\} \qquad (13)$$

If, for example, $q_0 = 1{\cdot}85$ and σ_0 is small in comparison, A will be about 0·69.

(III) I am not competent to discuss the observational aspects, but I suspect that it might prove difficult to discriminate between the present model and a cognate zero-pressure one. The observational properties of the latter are closely bound up with the function:

$$I(z) = \int_0^z dz\ \{1 + 2(q_0 + 1)z + (q_0 + 1 + 3\sigma_0)z^2 + 2\sigma_0 z^3\}^{-\frac{1}{2}}$$

The corresponding function in the present theory is:

$$J(z) = \int_0^z dz\ \{1 + 2(q_0 + 1)z + (q_0 + 1 - \sigma_0)z^2\}^{-\frac{1}{2}}$$

which can, of course, be expressed in terms of elementary functions. If it is the case that q_0 is considerably larger than σ_0, it would not be easy to distinguish between $I(z)$ and $J(z)$ for the range of values of z (the red shift) which have so far been observed.

(IV) We now introduce a second assumption.

Hypothesis B. Equation (5) holds also for the electron, with the same constant L.

The negative pressure in this case would be a tension counteracting the electrostatic tendency of the electron to fly apart. The resulting energy is of the form $\frac{4}{3}\pi R^3.LR^{-1}c^2$ and so proportional to R^2. Such an energy, interpreted as being due to surface tension, has recently been proposed by Dirac[3] in his theory of the muon as an excited state of the electron.

Hypothesis B gives:

$$L = \left(m\Big/\frac{4}{3}\pi a^3\right)a = \frac{3}{4\pi}\frac{m}{a^2},$$

where m and a are the mass and radius of the electron. Thus, in equation (10):

$$\frac{\sigma_0}{\sqrt{(q_0 + 1 - \sigma_0)}} = \frac{Gm}{a^2c}T_0 \qquad (14)$$

The radius of the electron is a theoretical concept and it is not entirely clear what value should be attached to it. We adopt Dirac's expression, $3e^2/4mc^2$. Inserting numerical values, equation (14) becomes:

$$T_0 = 2 \times 10^{19}\frac{\sigma_0}{\sqrt{(q_0 + 1 - \sigma_0)}}\ \text{sec} \qquad (15)$$

In terms of Hubble's parameter H, expressed as usual in km/sec per megaparsec, this is:

$$H = 1{\cdot}54\ \frac{\sqrt{(q_0 + 1 - \sigma_0)}}{\sigma_0} \qquad (16)$$

and this appears to be consistent with observation, for example, $H = 75$, $q_0 = 1{\cdot}85$, gives $\sigma_0 = 0{\cdot}03$, which is in the permitted range[4].

PHYSICS

Gravitational Deflexion of an Electromagnetic Wave

It is well known[1] that the velocity of propagation of an electromagnetic signal is governed by the boundary conditions imposed by the guiding structure, the type of modulation and the characteristics of the detector. It is possible that the velocity associated with an unmodulated transverse electromagnetic wave in free space may not be unique.

The deflexion of a light beam as it passes the Sun is calculated on Newtonian theory as:

$$\theta = \frac{2M}{av^2}$$

in astronomical units, where v is the velocity of the light corpuscles at infinity, M is the mass of the Sun, and a is the radial distance. For $v = c = 1$ this expression gives a deflexion equal to half that given by general relativity.

I have previously shown[2–4] that the constant velocity of light relative to any frame of reference may, in the steady state, be considered as a boundary condition imposed by the material boundary of the frame of reference. Physically, any electromagnetic energy arriving from a moving source may be considered to be guided in at c by the energy stored in the near fields associated with the current induced in the receiving aerial. Consider now the power density, P_r, of a wave transmitted into space by a dipole aerial. The distant field may be expressed in the usual form:

$$P_r = \frac{K}{r^2}(1 - \sin 2\omega t)$$

where K is a constant. The net transmitted power flow is associated with the first term inside the bracket and the velocity of propagation of this energy is c. If, however, this transmitted power is inherently guided by the stored energy component associated with the second term in the bracket, then it is the Sun's gravitational interaction with this stored energy term which is relevant to determining the deflexion of a light beam. The root-mean-square velocity, along the radius vector, associated with this stored energy term is simply $c/\sqrt{2}$ and the deflexion of a light beam is then:

$$\theta = \frac{4M}{a}$$

the same result as is predicted by general relativity.

Epitaxial Deposition of Cadmium Selenide

In the past few years there has been considerable interest in the use of evaporated films of cadmium selenide (CdSe) for thin-film transistors and photoconductive devices[1]. As normally prepared, such films consist of polycrystalline material which has a rather poor electron mobility.

We have found that it is possible to produce large-area single-crystal films of cadmium selenide in a conventional evaporator by using mica as an orientating substrate.

Photoconductive grade cadmium selenide is evaporated from an alumina boat on to freshly cleaved mica in an ambient pressure of 10^{-5}–10^{-4} torr. The mica substrate is mounted in an almost enclosed oven to give a uniform substrate temperature, and the cadmium selenide film thickness is monitored by optical reflexion through the substrate. Initial nucleation is performed at a temperature of 200° C, and evaporation is continued until the reflectivity has increased by about 20 per cent. The evaporation is then interrupted, the substrate temperature raised to 400° C, and the evaporation completed. Deposition rates of 100–150 Å/min are used at this latter stage, and the films built up to a total thickness of 750–3000 Å. Thicker films than this tend to flake off the substrate.

To illustrate the single-crystal nature of the films, Fig. 1 shows a transmission electron diffraction pattern of a 750 Å film. The whole area of the film produced (1·8 cm diam.) is single-crystal.

Fluid Displacement Phenomena in Porous Media observed by a Wide-line Nuclear Magnetic Resonance Method

Laboratory investigations of fluids moving through porous materials have been handicapped by the lack of direct methods of measuring fluid content without disturbing flow. Investigations of flow in porous media have been dependent on the properties of the particular tracer used to follow the flow. Experiments using labelled fluid have been criticized on the grounds that the movement of the tracer may not completely reflect the movement of the fluid.

The problem of measuring fluid content in porous materials has been studied extensively, however, and several methods have been developed through the use of various techniques, including electrical resistivity, X-ray absorption, radioactive tracers, neutron diffraction, magnetic susceptibility, and γ-ray absorption.

A new experimental method, based on nuclear magnetic resonance principles, which is free from the inherent limitations of the foregoing methods, was developed for examination of flow of fluids through porous media[1,2]. The sample to be investigated is placed within a coil and the amount of hydrogen-containing liquid is obtained directly by measuring the number of hydrogen atoms present inside this coil. No additional tracer is needed, since each hydrogen nucleus acts as its own tracer.

This method depends on the observation that if a sample containing nuclei with spin quantum number other than zero is placed in a direct-current magnetic field and is simultaneously irradiated by a small radio-frequency field rotating in a plane perpendicular to the steady magnetic field, the nuclei absorb radio-frequency energy at unique resonant frequencies proportional to the magnetic field strength[3]. The amount of energy absorbed by a liquid sample containing hydrogen atoms in its chemical constitution (such as water or hydrocarbon) is a measure of the number of hydrogen atoms in the observed volume.

In situ determination of fluid saturations in a miscible displacement experiment was performed for the first time without addition of a tracer through use of the nuclear magnetic resonance apparatus[1,2] and has already been reported[4]. This communication presents the results of detailed investigations of several miscible and immiscible displacement experiments conducted by displacing distilled water with deuterium oxide, kerosene with carbon tetrachloride and with deuterium oxide, and n-heptane with carbon tetrachloride in the presence of residual deuterium oxide in Boise sandstone cores.

...r magnetic resonance spectrometer developed ...tions of flow through porous media is ...nd the details of the experi- ...agnetic resonance ...ne flow samples

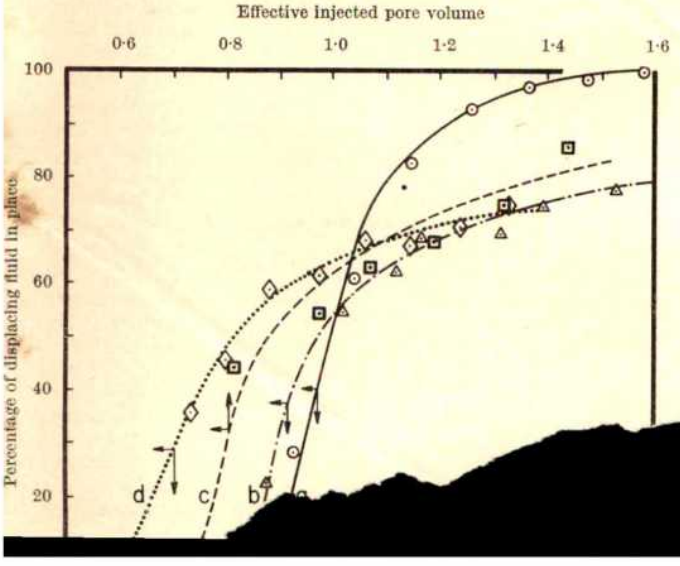
1 in. diameter) of the nuclear magnetic resonance apparatus. The nuclear resonance absorption spectrum was first observed under steady-state conditions and the derivative of the nuclear magnetic resonance absorption curve was obtained[2]. Then, the hydrogen-containing liquid was displaced vertically, from the bottom up, by a hydrogen-free liquid with a frontal velocity of the order of 10^{-3} cm/sec. The derivatives of the nuclear magnetic resonance absorption curves were obtained as the front between the hydrogen-containing and the hydrogen-free liquids was passing through the section at which the sample coil was located.

Since the nuclear magnetic resonance absorption signal amplitude is directly proportional to the number of hydrogen atoms present in the observed volume, provided the line width is the same, these experimentally obtained derivative curves were numerically integrated to obtain the nuclear magnetic resonance absorption signal amplitudes. The initial signal amplitude corresponds to 100 per cent saturation of the hydrogen-containing liquid. The saturation at subsequent intervals of injected pore volume were calculated by comparing the corresponding signal amplitudes with the initial signal amplitude.

In these experiments the line widths of nuclear magnetic resonance absorption curves were essentially the same, hence the signal amplitudes were used for comparison. In cases where the line width might change due to the wettability characteristics of the porous medium or changes in the viscosity of hydrogen-containing fluid, the area underneath the nuclear magnetic resonance absorption curve should be taken to be directly proportional to the number of hydrogen atoms present in the observed volume.

Using the procedure described, miscible displacement of distilled water with deuterium oxide (a hydrogen-free liquid) was observed. Although both the viscosity and the density ratios between distilled water and deuterium oxide, 0·80 and 0·90, respectively, were favourable, the concentration profile obtained was slightly asymmetric (Fig. 1*a*). This tailing of the breakthrough curve cannot be described by the one parameter diffusion model[4], which predicts a perfect S-shaped concentration profile having the 50 per cent concentration at one pore volume. Use of either two- or three-parameter dispersion models[5] to describe this concentration profile may indicate the presence of dead-end pores[6] or stagnant volume[5,7] in the Boise sandstone.

The effect of unfavourable viscosity ratio, 2·27, on the miscible displacement profile was observed by displacing kerosene with carbon tetrachloride. Viscous fingering of carbon tetrachloride is indicated by the early breakthrough and the greatly extended shape of the concentration profile (Fig. 1*b*).



In order to investigate a multi-phase fluid flow in a porous medium, a sandstone sample was saturated with deuterium oxide which was in turn displaced with *n*-heptane until a residual amount was left (this is indicated when the nuclear magnetic resonance absorption signal amplitudes stop increasing). The residual deuterium oxide saturation, 21 per cent, was measured by obtaining a nuclear magnetic resonance absorption signal from this flow sample and comparing its amplitude with that obtained from a similar sample with 100 per cent heptane saturation. Then, *n*-heptane was displaced with carbon tetrachloride and a highly irregular concentration profile was observed (Fig. 1*c*). Since this curve is plotted on an effective pore volume basis (79 per cent of the total pore volume), it is apparent from Fig. 1*c* that the presence of deuterium oxide has more effect than merely changing the porosity available to flow. The irregular shape of the concentration profile rather indicates a change in the pore size distribution caused by the presence of deuterium oxide. Since deuterium oxide is present in the core as the wetting phase, the non-wetting phase, *n*-heptane, can occupy only the larger pores, thereby resulting in a dendritic, non-wetting phase fluid distribution in which the large volumes of *n*-heptane are trapped in non-communicating blocks[6].

For a study of immiscible displacement, kerosene was displaced with deuterium oxide. A very early breakthrough of deuterium oxide did occur and its saturation increased steadily as more and more viscous fingers (viscosity ratio of 1·75) reached the sample coil (Fig. 1*d*).

process, regions of high concentration of one component remain, then such an aggregate may be too small to be segmented by the action of the mixer in a finite time, and diffusion out of the aggregate must take place before final mixing can occur.

In a barrel mixer, loaded axially as shown in Fig. 1*a*, the observed diffusion is a result of the particles acquiring a component of motion along the axis of the mixer. Figs. 1*a* and 1*b* illustrate the shear zone and two possible motions of the diffusion 'front' during mixing. (The diffusion 'front' is any hypothetical plane of constant composition perpendicular to the axis of rotation which signifies the progress of mixing at a given time.) If regions exist in the mixer in which a finite number of particles do not move into the shear zone, the diffusion 'front' will not be uniform. Thus, it must be established whether or not there are any systematic variations in concentration on any plane perpendicular to the axis of the mixer.

An idealized system of white and yellow beads, 200μ in diameter, identical in size, shape and densit[redacted] diff[redacted] in refractive index by 0·03 units, was ob[redacted] investigation. This permitted ready analy[redacted] taken from the mixer bed. These beads[redacted] axially in a simple barrel mixer, 4-in. diamet[redacted] length, constructed of 'Lucite'. Samples[redacted]

30,000	−1·33
50,000	−1·99
100,000	2·02

the observed and random variances are shown in Table 1. Thus, no systematic variation in concentration in a plane perpendicular to the mixer axis was observed in this system. It now remains to describe the particle motion in the mixer that leads to the observed diffusion as a plane front.

The principal mixing zones within a barrel mixer are shown schematically in Fig. 1*a*. Consider a plane *ABCD*, as shown in Fig. 1*c*, located within the shear zone of the mixture. Visual observations of motion in the mixer reveal that the great majority of particles enter this shear zone during each revolution of the mixer. The photographic investigation of mixing reported by Carley-Macauly and Donald (ref. 3, Fig. 12) illustrates this motion into the shear zone. Distributed at random across the plane *ABCD* are particles which may be considered to be half-spheres. For simplicity, consider that the centres of the particles all lie in the plane *ABCD*. Due to the gradient in the shear zone, particles passing over the plane *ABCD* will collide with those in the plane and are likely to be deflected. The deflexions result in a displacement of the particles parallel to the mixer axis. This is shown schematically in Fig. 1*d*, in which particle *Q* after collision with particle *P* moves in a direction along the mixer axis and into a 'hole' in the random assembly of particles.

The randomness of position within the assembly of moving particles and the action of a shear gradient are together the necessary and sufficient conditions to generate random motion of a particle in a mixer. Since one component of motion is parallel to the mixer axis, net diffusion will take place. As almost every particle enters the shear zone during each revolution, on the average, the diffusion 'front' is at all times a plane parallel to the original interface between the components of the mixture in an ideal system. Note that early investigations[4] revealed that density differences between components of the mix lead to collisions in the shear zone in which the resultant motion of the particles is predominantly toward or away from the centre of mass of the rotating charge.

Recent experimental analysis by Kaye and Sparrow[5] utilized a system of balls flowing down a stationary inclined plane in an attempt to simulate motion within a rotating mixer. They interpreted their results in terms of diffusion in the limited surface region, rather than in terms of diffusion within the more extensive shear zone, as shown in Fig. 1*d*. The results shown in Table 1 show that diffusion in solid–solid mixing cannot, as Kaye and Sparrow[5] suggest, be limited to a depth of eight or nine [redacted]meters from the free surface, but must occur [redacted] whole shear zone into which the great [redacted]les enter during each revolution. In the [redacted]d materials, limitation of diffusive [redacted]egion is unrealistic, since the shear [redacted] particle diameters in from the

GEOPHYSICS

Munro Jets and the Origin of Tektites

The theory of Spencer[1] that tektites splashed out of terrestrial craters met with support from Cohen[2], Gentner and Zähringer[3] and others, but also with objections, summarized by O'Keefe[4]. The main objection was that the air resistance of bodies as small as tektites on their upward flight is too large to allow them to escape from the crater at the velocities (2–8 km/sec) required for their observed ranges. Vand[5,6] proposed a detailed mechanism of a tektite jet formation through an implosion of a conical cavity lined with molten glass which is formed immediately after impact, and showed that a jet of tektites can survive the upward atmospheric journey if of sufficient total mass; that is, if it originated in a crater more than some 4 km in diameter. The escape is further facilitated by the low density of the hot train left after the passage of the meteorite. The high-velocity jet overtakes the general debris and keeps tektites from crystalline contamination. If moldavites are from the 24 km diameter Ries Kessel crater in Germany, the tektite jet from an initial conical cavity 4 km deep and 1 km in diameter would be a cylinder about 5 km long and 40 m in diameter, moving initially at 2·36 km/sec and carrying some 10^{10} kg glass with it. The original of the required cone wall implosion velocity of about 0·15 km/sec was not well understood, as such a phenomenon had not then been observed in laboratory cratering experiments, and gravity collapse could only account for part of the velocity.

However, the work of Watson and Gibson[7] on jets formed from imploding bubbles seems adequately to elucidate the operating mechanism. Photographs are given of beautiful Munro jets formed when hemispherical cavities on the surface of a liquid are collapsed by a shock-wave travelling from below. Shock strength of some 10 kbar produces 1·9 km/sec Munro jets from cavities in water.

After a meteoritic impact, a travelling sh[illegible] be reflected upwards from underlying d[illegible] Reflexion and refraction of shock-wav[illegible] phenomena. For acoustic waves[illegible] travelling from medium 1 to m[illegible]

Typical boundaries which may be encountered under terrestrial conditions at smaller depths are those of granite (d = 2·65, c = 5·5 km/sec) over diorite (d = 2·9, c = 6·5 km/sec) or at depths of some 40 km (Mohorovičić discontinuity) of diorite over dunite (d = 3·4, c = 7·75 km/sec). We find for P_r/P_i for the above two cases 0·12 and 0·16 respectively.

Assuming that Ries Kessel was formed by an iron meteorite 1 km in diameter travelling at 15 km/sec and having kinetic energy equivalent to 10^5 megaton TNT, we find by analogy with nuclear explosions that a 100 kbar shock would be found at 2·5 km from the blast centre. According to Shoemaker[8], the blast centre occurs at 4 to 5 meteorite lengths after ground penetration. Assuming that the meteorite arrived at an angle 30° from horizontal, as required by the range of moldavites, the centre of explosion would be at 2 km depth and therefore a downward travelling 100 kbar shock would be found at 4·5 km depth. If at this depth there happened to be a discontinuity reflecting about 15 per cent of pressure, an upward travelling 15 kbar wave would form, which would attenuate to 10 kbar when reaching the cavity.

The implosion velocity which occurs on the arrival of the reflected wave is a spalling effect due to its reflexion at the free cavity interface. The implosion velocity at the free interface is then twice the instantaneous particle velocity, which is given by $v = P_s/c\,d$, where c and d are the velocity of propagation of the longitudinal wave and density at shock pressure P_s. Substituting for glass d = 2·5, c = 5 km/sec, P_s = 10 kbar, we obtain v = 75 m/sec or the implosion velocity $2v$ = 0·15 km/sec, which is just the required value for the cavity collapse to generate a backsplash jet of the required velocity.

We may further speculate that the general inward motion of other crater materials caused by the passage of waves reflected from below will also be responsible for the formation of a central peak in some craters, if underlain by denser strata at favourable depth. In fact, the central peak of Steinheim basin may have been formed through reflexion at the underlying limestone-granite boundary, and the peaks of certain other large craters through reflexion from Mohorovičić discontinuity. Similar interpretation of central peaks of lunar craters might help in mapping such discontinuities under the lunar surface.

GEOLOGY

of Silcretes of Central Australia

[illegible], Stephens[1] has suggested that the wide-[illegible]tes of Central Australia can be explained by a [illegible]ree events: (1) mobilization of silica by

Although Stephens's concept of linking the lateritic leaching processes in one great region with the deposition of silica in the adjacent one is appealing in its simplicity, severe doubts come to mind if one attempts to visualize the process of fairly regular distribution of the silica over a surface, measuring hundreds of miles across, by means of streams and rivers. No planation surface is so featureless as to allow complete, or major, inundations by rivers, and even during great floods, rivers would, therefore, tend to follow particular linear trends along which the silica supplied and eventually precipitated would have to be confined. Thus, if rivers flowing across the region actually did contribute a major amount of allochthonous silica to the formation of the silcrete sheet, this could only have happened by feeding the dissolved silica into the groundwater and by its further slow distribution and rise with this latter agent away from the river courses. It is more likely, however, that river contributions of silica were subordinate or negligible, and that the formation of the siliceous duricrust followed, predominantly or entirely, the pattern generally accepted for the genesis of such surficial encrustations, whether ferruginous, aluminous, manganiferous, calcareous, or siliceous—mobilization of the substances concerned from the bedrock (or parent material) *in situ* by chemical weathering, and precipitation after movement over very short, or at best moderate, distances in the groundwater, usually by means of evaporation[2]. It would be necessary, therefore, to make allowance, in the silcrete areas, for a period during which the climatic conditions were just right for both mobilization and precipitation of silica to occur more or less *in situ*. A climate drier than the equatorial one with its lateritic weathering processes would presumably have to be envisaged.

My own experience with duricrusts was essentially gained in West Africa, and although I was predominantly concerned there with ferruginous and aluminous types[3,4], I have made some observations on siliceous precipitates which support the generally accepted view outlined here. These investigations will be published separately.

W. D. Brückner

[4] Bruckner, W. D., *Eclogae Geol. Helv.*, **50**, 239 (1957).

I take Prof. Brückner's remarks to mean that he almost exclusively favours the hypothesis of relative accumulation of silica within the profile in which it has been released by weathering. Examples of this are widespread in Australia for both laterite and silcrete, but in the case of the Central Australian silcretes the general and detailed evidence is markedly in favour of absolute accumulation following lateral movement in drainage waters. In addition to the general evidence set out in my letter the following details are significant. (1) Water-worn quartz gravels are frequently found in the matrix of silcrete. (2) Water-worn silcrete from some higher residuals is often included in the silcrete of lower surfaces, thus pointing to a complex erosional and depositional history rather than simple widespread planation. (3) Some of the silcrete overlies gypseous, calcareous and alunitic lacustrine deposits from which it is most unlikely to have been derived. (4) The present ephemeral stream pattern and the associated soils and rock exposure taken together with the higher situated water-worn quartz gravels point to topographic inversion of a landscape in which the originally lower silicified surfaces are now preserved as the higher topographic elements.

It is my intention to complete, during 1966, a monograph giving the results of an intermittent, but very prolonged, investigation of Australian laterites and silcretes and their relationships.

Cromer Forest Bed Series

During the past seven years much new evidence has been obtained concerning the stratigraphy of the Cromer Forest Bed Series of the Norfolk and Suffolk coasts, and this requires the sequence put forward by Clement Reid[1,2] to be revised. These new investigations have not yet been completed and it will be some time before the full stratigraphical and palaeoecological results will be available. But because of the importance of the Cromer Forest Bed Series for the European Middle Pleistocene succession it will be of general interest to give a simplified description of our provisional stratigraphical results.

Reid's classic Cromer Forest Bed Series succession is shown in Table 1.

Lower Freshwater Bed	
Weybourne Crag	

The only emendation that this sequence has received since the nineteenth century is Solomon's[3] suggestion that the Arctic Freshwater Bed precedes the *Leda-myalis* Bed.

The new stratigraphical evidence is summarized in the sketch-sections of Figs. 1 and 2 of the coastal exposures at West Runton and Mundesley. A lower temperate series, principally estuarine sediments (*a*), is overlain by sands and gravels (*b*), often ferruginous near their surface and forming iron pan. These gravels are often associated with clay-conglomerates derived by re-working of the lower estuarine beds. Arctic freshwater beds (*c*) are associated with these gravels at West Runton, and ice-wedge casts and involutions occur within them. Freshwater late-glacial marls and silts (*d*) lie on these beds and then come the temperate organic mud beds (*e*) forming the so-called 'Upper Freshwater Beds' at West Runton. These temperate freshwater beds are the type sediments of the European Cromerian Stage[4]. The soil (*f*) of this stage extends north and south of the main exposure at Goss' Gap, West Runton. Along this stretch of the coast the soil and the peat are covered by estuarine silts, gravels and sands (*g*) of a marine transgression which occurred in the latter half of the Cromerian. The well-known bed of *Mya truncata in situ* at West Runton, noted by Trimmer[5],

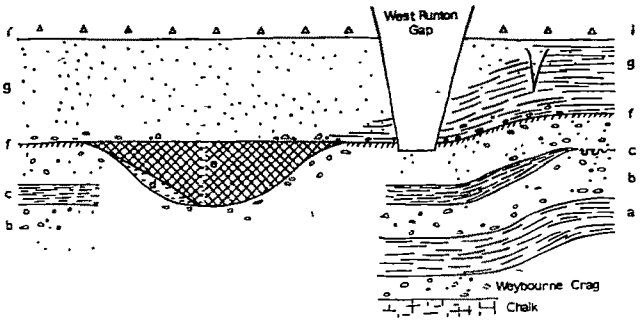

Fig. 1. Sketch section at West Runton, about 400 m length and 7 m depth. Key to letters in Table 2

appears to be the soil of the Cromerian land surface bored by *Mya* in the first stages of the transgression. At Mundesley the transgression silts and beach gravels of the same transgression cover thin temperate peats of the Cromerian freshwater episode, which lie in hollows of the ferruginous gravels and sands of horizon (*b*). Similar transgression silts occur at Corton in Suffolk overlying the freshwater 'Rootlet Bed', which again lies on ferruginous gravel.

At Mundesley, freshwater sediments (*h*) again occur over the transgression deposits. They are arctic in character and are associated with ice-wedge casts and involutions. Similar ice-wedge casts penetrate the transgression deposits at Corton, and at West Runton. The succession is capped by the lowest till (*i*) of the coast sections, representing the first ice advance over East Anglia.

Regarding the correlation of these temperate and cold horizons, the lower temperate series may be equivalent in age to the topmost temperate horizon (*L*5) of the Ludham borehole[6]. This temperate stage is provisionally named 'Pastonian' as the sediments occur on the foreshore and in boreholes opposite Paston Cliffs, near Mundesley.

Table 2

Stage	Deposit (letters refer to Figs. 1 and 2)	Environment	Identified by C. Reid as:
Lowestoftian	*i* Till	Glacial	Cromer Till
	h Mossy silts, sands	Cold freshwater	Arctic Freshwater Bed
	Ice-wedge casts and involutions	Permafrost	
Cromerian	*g* Silts, sands	Temperate estuarine, marine	*Leda-myalis* Bed
			Forest Bed (estuarine)
	f Soil	Temperate	
	e Muds, peats	Temperate freshwater	Upper Freshwater Bed
Beestonian	*d* Silty marls	Late-glacial freshwater	
	c Silts	Cold freshwater	Arctic Freshwater Bed
	b Gravels, sands, clay-conglomerates	Cold	Forest Bed (estuarine)
	Ice-wedge casts and involutions	Permafrost	
Pastonian	*a* Silts and sands	Temperate estuarine, marine	Weybourne Crag

The middle cold horizon appears to be a hitherto unrecorded cold stage, here named the 'Beestonian' because the characteristic arctic beds of the stage are well exposed in the Beeston Cliffs, near Sheringham. The upper temperate horizon, including both freshwater and estuarine facies, must be included in the Cromerian Stage by definition. The stage names and their boundaries shown in Table 2 are given according to the system described by West[7].

Reid's divisions are not everywhere comparable with those of the sequence described here. Table 2 shows the general relation of the two sequences as far as possible: we have not included in this the Lower Freshwater Bed, as the identity of this is not yet certain. It will be best to abandon the names suggested by Reid, as neither the sequence nor the divisions can be maintained.

This work has been supported by a Nature Conservancy grant. We thank the Paramoudra Club of Norwich and Mr. R. A. Markham of Ipswich Museum for their help in excavations made at West Runton.

CRYSTALLOGRAPHY

Nature of the Twinning in the Lower Strontium Soaps

Morley and Vand[1] have proposed the space group $P2_1/n$ for strontium laurate. During the investigation of the structure of strontium caprylate I found[2] that the crystals were all twinned and upper-layer Weissenberg and precession photographs showed conclusively that the crystals were triclinic with the remarkable feature of $\beta^* = 90°$.

Crystals of strontium caprate and strontium laurate, prepared by metathesis, have now been grown by slow cooling of aqueous solutions. The crystals so formed are rather less perfect than those of the caprylate but are quite good enough to confirm that all three soaps are of the same form; all are triclinic and in all cases $\beta^* = 90°$.

The twinning shows up clearly in the [100] projections of the soaps, where the two members of the twin have a common c^* axis. In strontium laurate the angle between the c^* and b^* axes (γ^*) is such that the reflexions from the two members of the twin with k even coincide exactly. A diagram of the composite reciprocal lattice plane is shown in Fig. 1. In the caprate and caprylate, although the twinning reveals itself in the same way, the coincidence of the reflexions on the rows when k is even is no longer exact.

The structures exhibited some unusual symmetries. The [100] projection shows that the Fourier transform of the unit cell contents contains a mirror plane but, since the reciprocal net is non-orthogonal, the weighted reciprocal lattice itself does not exhibit the mirror plane.

The probable mode of twinning is across the (001) planes at the ends of the hydrocarbon chains. In this plane, remote from the ionic groups, there will be little difference in energy between the two orientations. Fig.

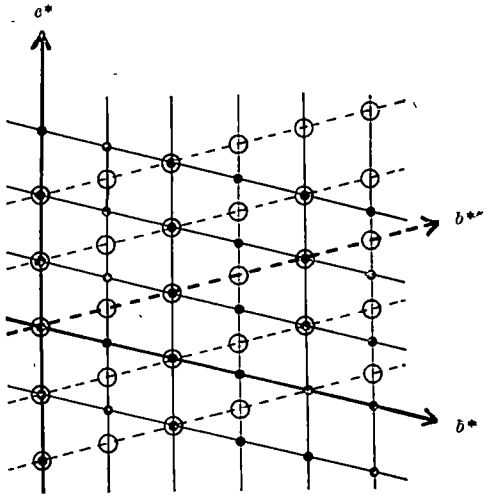

Fig. 1. The composite reciprocal lattice of the [100] projection

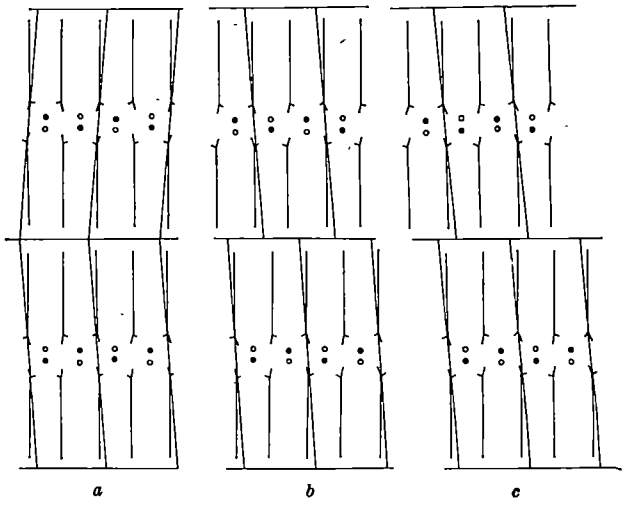

Fig. 2 *a*, The twinning mode; *b*, stacking fault with a slip of *b*/2; *c*, stacking fault with a slip of *b*/4

2*a* shows a sketch of the unit cell and the twinning mode. Since the angle β*, that is, the angle between the (100) and (001) planes, is exactly 90° the two lattices of the members of the twin coincide exactly in the [010] projection. It is interesting to note that the mode of twinning preserves the continuity of the lines of apparent symmetry across the twin plane.

In addition to the twinning in all three soaps there is evidence of a stacking fault. This reveals itself in the streaking of some sets of reflexions in the *c** direction. This fault probably originates in the same plane. A shift of *b*/2, as shown in Fig. 2*b*, would bring the ends of the hydrocarbon chains into a similar environment, and the influence of the ionic groups, 12 Å or more away, is likely to be very small. Such a stacking mistake would restrict the streaking to the reflexions when *k* is odd. Alternatively a shift of *b*/4, illustrated in Fig. 2*c*, would result in the continuity of the apparent line of symmetry across the fault plane and only reflexions with $k = 4n$ would be sharp. The first proposed mode agrees better with the observations. There is no streaking at all on the (00*l*) reflexions and the streaking of the (0*kl*) reflexions is greater when *k* is odd, but there is some streaking of the reflexions with *k* even. There is no observable difference in the sharpness of reflexions for which $k = 4n$ and $k = 2(2n + 1)$.

CHEMISTRY

A C23-type Modification of $ThAs_2$

$ThAs_2$ was reported to crystallize in the tetragonal Cu_2Sb or *C*38 type of structure[1]. In an attempt to synthesize this phase by reacting arsenic with thorium powder at temperatures between 600° and 900° C, a new modification was obtained. This low-temperature form α-$ThAs_2$ is orthorhombic and of the *C*23 type. Its lattice constants are:

$$a = 7{\cdot}287 \pm 3 \text{ Å}$$
$$b = 9{\cdot}784 \pm 4 \text{ Å}$$
$$c = 4{\cdot}002 \pm 2 \text{ Å}$$

The same structure type is also found in $ZrAs_2$ (ref. 2), $HfAs_2$ (ref. 3), TiP_2, ZrP_2 and HfP_2 (ref. 4). The transition to the tetragonal high-temperature modification β-$ThAs_2$ appears to occur at approximately 1,100° C. A sample held at 1,150° C for one day was in parts converted into the *C*38 modification.

Our α-$ThAs_2$ samples showed *p*-type thermoelectric power of 10–20 μV/°C at room temperature and a diamagnetic susceptibility $\chi_M = -47{\cdot}10^{-6}$ cgs units/mole at 80° and 300° K. Both modifications were found to be metallic. This result is not trivial in the case of α-$ThAs_2$. In the ordinary *C*23 type the co-ordination is:

$$M\text{—}5X_I + 4X_{II},\ X_I\text{—}5M,\ X_{II}\text{—}4M$$

Six of the neighbouring anions form a trigonal prism around the cation while the remaining three anions are located outside the square prism faces coplanar with the cation. For large cations, such as Pb^{2+} in lead chloride, this co-ordination leads to a rather dense packing so that one might attribute its occurrence to geometry only. However, three of the nine Cl neighbours of each Pb are considerably closer ($2Cl_I$ at 2·67 Å, $1Cl_{II}$ at 2·89 Å) than the rest (at 3·06, 3·09, 3·14 and 3·30 Å), indicating that the electron configuration of the cation is also of importance: Pb^{2+} readily forms *p* bonds. Hybrid wave functions fitting the actual 9-co-ordination of the cation can be constructed by admixing an *s* and all five *d* orbitals to the *p* functions. If, therefore, in addition to geometry the electronic configuration of the cations is also important, then one would expect the *C*23 structure to occur in connexion with cations which have all five *d* orbitals available for bond formation. To our knowledge, there are no cations which contain localized *d* electrons and show a 9-co-ordination.

Among the non-transition elements, above all Ba^{2+}, but also Pb^{2+}, fit both criteria and it is not surprising, therefore, that their halides are the main representatives of the *C*23 structure. A tetravalent cation is needed in order that the bonds in *C*23-type chalcogenides be saturated, and this is indeed the case in the non-metallic phases ThS_2 and $ThSe_2$. A pentavalent cation such as Pa^{5+} may form PaPS, PaAsS, etc., which we think may be isostructural with Pb(OH)Cl (*C*23-type with X_I and X_{II} being different anions). Extrapolating further one might expect hexavalent cations to be associated with the *C*23-type phosphides and arsenides. This is obviously not the case in the $ZrAs_2$ family of compounds, and their adherence to the *C*23 structure seems rather surprising at first glance. However, the *C*23 structure of the $ZrAs_2$ family differs from the ordinary $PbCl_2$ structure in that the corresponding atomic parameters give rise to bonded zig-zag chains involving half the anions. Ideally, bond saturation may therefore again occur with tetravalent cations, as can be seen from the representative ionic formula $Zr^{4+}As^{3-}As^{-}$. Although the anion–anion distances within the chains in $ZrAs_2$ and $HfAs_2$ are too long to correspond to single bonds, the 'strive' towards bond saturation is nevertheless obvious in these compounds. Due to the larger size of the cation the chain formation will be less pronounced in α-$ThAs_2$. I do not know the exact As–As distance in α-$ThAs_2$ since I did not determine the atomic parameters, but it is probably around 2·7 Å. The metallic behaviour of my samples gives further evidence that the As–As distance within the chains is longer than the single-bond diameter of arsenic (2·42 Å, ref. 5). Since phases, the bonding of which nearly satisfies the conditions for semiconductivity, are often superconductors, α-$ThAs_2$ was also tested for superconductivity properties. However, down to 1·2° K, no transition to the superconducting state was found[6].

As would be expected, the metallic character of the high-temperature modification is more pronounced. Indeed, no anion–anion bonds occur in the *C*38 structure of β-$ThAs_2$ so that saturation of the bonds is impossible. In this connexion it should be noted that in the corresponding isostructural uranium compounds, UP_2, UAs_2

and USb_2, the uranium atoms do not contribute all their six valence electrons necessary to fill up the anion valence shells, and as a consequence these compounds are also metallic.

Attempts to prepare the diphosphide ThP_2 always failed. Instead of ThP_2 almost pure Th_3P_4 of the cubic $D7_3$ type formed, which is a semiconductor like the isomorphous Th_3As_4. It would be expected, however, that ThP_2 exists and that it is isomorphous with α-$ThAs_2$. Six faint low-angle lines which I observed on my X-ray photographs, and which do not belong to the Th_3P_4 pattern, can indeed be attributed to a $C23$ type ThP_2 with the following lattice constants:

$$a = 6{\cdot}95 \text{ Å}$$
$$b = 9{\cdot}42 \text{ Å}$$
$$c = 3{\cdot}90 \text{ Å}$$

I thank Miss E. Viefhaus and Mr. H. U. Boelsterli for assistance in the X-ray work and sample preparation, and Dr. E. Mooser for advice.

New T_3B_7 Compounds

In the course of a study on transition-element compounds of composition TB_2 (T = transition element, B = phosphorus-group element) two compounds with a body-centred cubic structure were found, a semiconducting one in the system Re–As and a metallic one in the system Mo–Sb. Both compounds formed on reacting, at 600°–900° C, the powdered elements in various ratios. A crude analysis of $ReAs_x$ by thermal dissociation at 1,000° C gave $x \approx 2{\cdot}4$. Our arsenide, therefore, must be identical to the phase $ReAs_{2.3}$ reported by Wiechmann *et al.*[1]. The non-metallic behaviour as well as the diamagnetism of rhenium arsenide confirmed the suspected stoichiometry Re_3As_7 which corresponds to the normal valencies of Re and As. From density measurements, the unit cell [$a = 8{\cdot}722 \pm 2$ Å] was found to contain four formula units of Re_3As_7. Since in the X-ray diagram only the general extinctions for body-centred cubic symmetry are observed, seven space groups are possible. However, the striking resemblance between the diagram of Re_3As_7 and that of Ir_3Ge_7 led me to postulate a $D8_f$ structure for Re_3As_7. Best agreement between calculated and observed intensities was obtained for the following parameter values:

$$x_{Re} = 0{\cdot}338, \quad x_{As} = 0{\cdot}159$$

Assuming the $D8_f$ type to be correct* for Re_3As_7, the coordination is as follows:

Re —4As_{II} in 2·50 Å	As_I — 4Re in 2·60 Å
4As_I in 2·60 Å	
1Re in 2·83 Å	As_{II} — 3Re in 2·50 Å

This proximity is, in fact, reasonable since it makes allowance for saturated covalent bonds as can readily be seen by invoking a charge transfer $Re_3^+As_3^-As_4$ and by allowing half-bonds to form between Re and As_I. The non-metallic character of Re_3As_7 was established by resistivity measurements on sintered samples at temperatures above 300° C. Assuming $\rho \approx \exp(\Delta E/2kT)$, an energy gap $\Delta E \approx 0{\cdot}7$ eV was derived. At room temperature the samples were n-type with a thermoelectric power of about 100 μV/°C. The magnetic susceptibility χ_M was found to be -210 and -250×10^{-6} cgs units/mole at liquid-nitrogen and room temperature, respectively.

As expected, the corresponding technetium arsenide occurs in the same structure with $\alpha = 8{\cdot}702 \pm 2$ Å.

Attempts to prepare the corresponding rhenium antimonide failed. Rhenium did not react with antimony up to 1,300° C. The phosphide Re_3P_7 has a different structure and is isomorphous with $Re_3As_4P_3$ and $Re_3As_3P_4$.

The second compound, Mo_3Sb_7, is metallic and has a practically temperature-independent paramagnetism (+570 and $+580 \times 10^{-6}$ cgs units/mole at 80° and 300°, respectively). The crystallographic data of Mo_3Sb_7 are†:

$a = 9{\cdot}569 \pm 2$ Å, $D8_f$ type with $x_{Mo} = 0{\cdot}341$, $x_{Sb} = 0{\cdot}161$

A survey[2] of all previously known $D8_f$-type compounds (Table 1) shows that they are metallic and that in them the total number of valency electrons per formula unit (counting all outer d electrons of the transition element) lies between 51 and 55. The occurrence of the $D8_f$ structure in Mo_3Sb_7 therefore is less surprising than in the non-metallic arsenides Tc_3As_7 and Re_3As_7, the valency electron number of which is 56.

I have tried to supplement the list of $D8_f$ compounds by preparing a series of binary and ternary phases of adequate composition (see Table 1). These attempts were successful only in a few cases:

$Ir_3Ga_4Ge_3$	: $a = 8{\cdot}702 \pm 3$ Å
$Ir_3In_4Sn_3$	: $a = 9{\cdot}371 \pm 2$ Å
$Ir_3Ga_3Ge_4$	: $a = 8{\cdot}694 \pm 3$ Å
$Ir_3Ga_3Sn_4$	: $a = 9{\cdot}113 \pm 2$ Å
$Ir_3In_3Ge_4$	: $a = 8{\cdot}980 \pm 2$ Å
$Ir_3In_3Sn_4$	: $a = 9{\cdot}369 \pm 2$ Å
$OsIr_2Sn_7$	: $a = 9{\cdot}367 \pm 3$ Å

All my samples were prepared either by sintering the components in the form of pressed powder pellets or by melting, quenching and subsequent annealing at temperatures between 450° and 900° C. Since all $D8_f$ compounds form peritectically, it is possible that these preparation techniques are inadequate in many of the systems investigated and that the failure which I incurred in synthesizing the compounds in parentheses in Table 1 does not necessarily exclude their existence. Fortunately, in the case of Ru_3Sn_7, Ir_3Ge_7, Ir_3Sn_7, $Ir_3Ga_3Sn_4$, $Ir_3In_3Sn_4$ and $Ir_3In_4Sn_3$, the peritectical transformation occurs at a high temperature (between 700° and 900° C). On cooling, the solidified reguli suddenly start to glow, indicating a very rapid exothermal peritectical reaction. In the case of Ni_3Ga_7, on the other hand, the transformation occurs at 250° C (ref. 3) and is accordingly slow.

Thermoelectric Power and Chemisorbed Hydrogen

Chemisorption and catalysis on palladium have been attributed to holes in the *d* band of the metal[1]. Earlier work has shown that ambient gases change the thermoelectric power of silver[2] and copper[3]. The present communication demonstrates how simultaneous measurements of thermoelectric power and resistance show how chemisorbed hydrogen affects the Fermi-level of palladium at the metal–gas interface.

A 7-mg film of palladium of geometrical area 175 cm² was formed by evaporation of a wire in high-vacuum on to the glass walls of a reaction vessel. After annealing, the film shows a thermoelectric power of $-7{\cdot}5$ μV deg.$^{-1}$ compared with $-9{\cdot}5$ for bulk palladium[4]. Hydrogen gas was admitted to the film at 20° C, and the hydrogen uptake, resistance and the thermopower of the film all measured for various uptakes. Fig. 1 shows that the resistance of the film is raised by chemisorbed hydrogen, as found by Suhrmann[5], and the thermopower changes in the positive direction. Point *M* denotes monolayer coverage estimated for atomic adsorption on the geometric area.

Like Surhmann[5], we assume a surface dipole $Pd^{\delta+}-H^{\delta-}$, on the basis of surface dipole measurements for other transition metals[6]. Such chemisorption will tend to lower the Fermi-level and, assuming the usual density of states picture for palladium, nickel and platinum as in Fig. 2 (ref. 7), this means an increase in $N_d(E)$ since the Fermi-level lies above the maximum. The following two equations for thermopower S and the conductivity σ ($\propto (1/R)$) are relevant[8]:

$$S = -\frac{\pi^2 k^2 T}{3|e|}\left\{\frac{\partial \ln \sigma(E)}{\partial E}\right\}_{E=\zeta} \qquad (1)$$

$$\sigma = \text{const}\ lA = \text{const}\ 'A/N_d(\zeta) \qquad (2)$$

$\sigma(E)$ denotes the conductivity calculated as if the Fermi-level was at energy E, and the differential coefficient is taken at the true Fermi-level $E = \zeta$. The electronic charge is $-|e|$. In equation (2), A denotes the area of the Fermi surface, and l the mean free path of the electrons. A is a measure of the number of electrons at the Fermi surface, which is quite distinct from the total number of electrons discussed in earlier resistance work[5].

According to Mott[7], the current in transition metals is carried by *s* electrons, which are trapped by holes in the *d* band, so that $l \propto 1/N_d(\zeta)$, where $N_d(\zeta)$ is the density of states in the *d* band at the Fermi surface (see also ref. 8, p. 377). Substituting for $\sigma(E)$ in equation (1) gives:

$$S = -\frac{\pi^2 k^2 T}{3|e|}\left\{\frac{\partial \ln A}{\partial E} - \frac{\partial \ln N_d(E)}{\partial E}\right\}_{E=\zeta} \qquad (3)$$

The relatively high resistance of transition metals has been attributed[7] to the $N_d(\zeta)$ factor in equation (2). If we assume this is dominant in changes in S, $\Delta_c S$ due to chemisorption effecting changes in the Fermi-level from $\zeta(M)$ to $\zeta(M^+-H^-)$ in Fig. 2 is given by:

$$\Delta_c S = \frac{\pi^2 k^2 T}{3|e|}\,\Delta_c\left\{\frac{\partial \ln N_d(E)}{\partial E}\right\}_{E=\zeta} \qquad (4)$$

If hydrogen chemisorption raises $N_d(E)$, then according to equation (4) we expect a positive variation of S, and according to equation (2) a decrease in σ (increase in R), both of which are found. We conclude, in contrast to copper[3], that for palladium the main effect of adsorbed gas on electron transport properties is exerted through the scattering or 'mean free path' term. This was really to be expected, if for transition metals the conduction electrons are *s* electrons, since we do not expect much change in A_s (as distinct from A_d), the area of the Fermi surface in the *s* band, with energy E, so the first differential in equation (3) is small. We would point out that, for a transition metal where the Fermi-level lies below the maximum of $N_d(E)$, electron abstraction chemisorption will cause a negative variation of S and a decrease in R.

From the practical point of view the changes in S are some fifty times greater than in R, hence S is a much more sensitive indicator of electronic changes in Fermi-level due to chemisorption. After about one-quarter of the palladium surface is covered by hydrogen, S starts to decrease again. This effect may be due to a change-over from one lattice plane to another. An alternative possibility is a change-over from chemisorbed H^- to H_2^+, as first noted from surface potentials[9]. S may also indicate chemisorption on defects and dislocations if present in sufficient concentration. We have so far made measure-

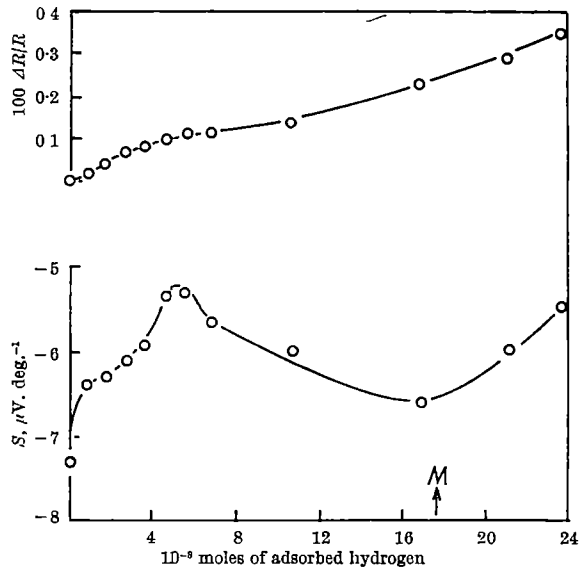

Fig. 1. Percentage change in film resistance $100\Delta R/R$ ($R = 45\Omega$) and changes in thermoelectric power S with 10^{-8} moles of adsorbed hydrogen. *M* denotes the monolayer

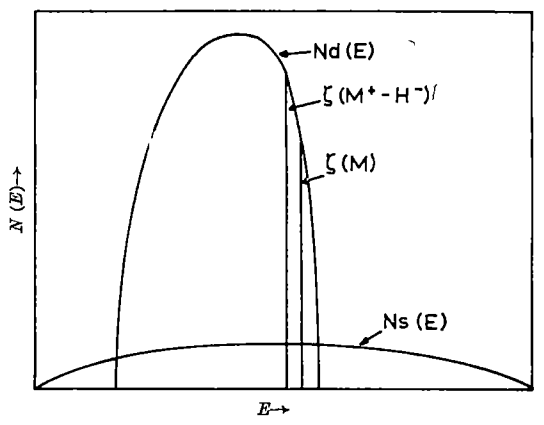

Fig. 2. The density of states diagram for palladium (also nickel, platinum) showing the way the Fermi-level changes from $\zeta(M)$ to $\zeta(M^+-H^-)$ when electrons are transferred from the metal to the chemisorbed hydrogen

ments on palladium, nickel, rhodium and platinum, and we intend to extend our measurements to other metals, and to investigate how the Fermi-level changes during an actual catalytic reaction. The foregoing theoretical treatment with further development should enable us to correlate resistance and magnetic measurements during chemisorption, which has not been satisfactorily achieved to date.

Study of some of the Parameters involved in Split-stream Chromatographic Injection

The two essential requirements placed on a split-stream injector are that: (1) the injected sample be uniformly distributed in the split stream as the splitting point is reached; (2) the width of the splitted portion entering the column be appreciably smaller than the eventual width of all the eluted components.

It will be assumed in the investigation that follows that the injected sample, if liquid, is not vaporized sluggishly, and that the wall of the mixing tube connecting the injected point to the splitting point does not retain the sample. The first of these effects would interfere with good sample distribution in the split stream, and the second would cause tailing of the portion injected in the column.

Let L, S, D and F designate the length and cross-section of a round mixing tube, the diffusion constant of some component of interest and the volumetric flow of the split stream. The time required for substantial diffusion of a molecule packet across the mixing tube is of the order of S/D and the time $a\,S/D$ will be allotted to this event, a being a 'safety factor' larger than unity intended to allow for nearly completely uniform diffusion of the component in the mixing tube. The velocity of the carrier gas being F/S, the length of an adequately long mixing tube should be at least the product of that velocity times the allotted diffusion time, that is:

$$L \geqq a \frac{S}{D} \cdot \frac{F}{S} = a \frac{F}{D} \qquad (1)$$

This length is notably independent of tube size.

The height equivalent to a theoretical plate (H) of the mixing tube is given by the expression:

$$H = 2\frac{DS}{} + \frac{F}{24\pi D}$$

and since fairly large splitting ratios will be aimed at, for which the velocity will be appreciably higher than that required for minimizing the expression above, H will be given with sufficient accuracy by:

$$H \cong \frac{F}{24\pi D}$$

The space variance of any component distribution after travelling along the mixing tube of length L will be LH and the volumetric variance will be:

$$W = S^2 L H = S^2 a \frac{F}{D} \frac{F}{24\pi D} = \frac{a}{24\pi} \frac{S^2 F^2}{D^2}$$

Let N designate the splitting ratio. The volumetric variance w of the component entering the column will be:

$$w = W = \frac{a}{24\pi} \frac{S^2 F^2}{N^2 D^2}$$

and its space variance will be:

$$\frac{w}{s^2} = \frac{a}{24\pi} \frac{S^2 F^2}{N^2 D^2 s^2}$$

where s designates the open tubular column cross-section. This variance should be appreciably smaller than the variance of the inert component eluting from the column, which is itself smaller than the variance of the retarded components. This variance is, at optimum velocity:

$$l \sqrt{\frac{s}{3\pi}} = \frac{1}{3\pi} n s$$

where l designates the column length, and n its number of plates.

At optimum velocity for any component, the column flow is a fraction $1/c$ of the optimum flow for the inert component, c being usually between 2 and 3:

$$f = \frac{1}{c} D \sqrt{48\pi s}$$

hence:

$$F = Nf = \frac{N D}{c} \sqrt{48\pi s} \qquad (2)$$

and we should have:

$$\frac{a}{24\pi} \frac{S^2 F^2}{N^2 D^2 s^2} = \frac{a S^2 48\pi N^2 D^2 s}{24\pi c^2 N^2 D^2 s^2} \leqq \frac{1}{b} \frac{ns}{3\pi}$$

or:

$$S \leqq c s \sqrt{\frac{n}{6\pi a b}} \qquad (3)$$

where b designates a second 'safety factor', larger than unity, designed to ensure that the main contribution to any band variance is that due to the band passage in the column.

Substituting the value of F from equation (2) in equation (1) we obtain:

$$L \geqq a N \sqrt{48\pi s} \qquad (4)$$

Equations (3) and (4) constitute two essential constraints on the mixing tube, giving as they do an upper bound on its cross-section and a lower bound on its length.

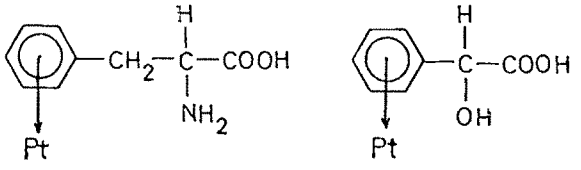
Stereospecific Catalytic Labelling of Amino-acids and Mandelic Acid with Isotopic Hydrogen



A comparison has been made between the catalytic labelling[1] of organic compounds with deuterium and tritium and radiation-induced techniques[2]. Of fundamental importance in deciding the choice of method, particularly for tracer applications, is the possible change in configuration which may occur during substitution by isotopic hydrogen. In radiation-induced procedures, a preference for retention of configuration has been observed in crystalline systems such as the octyl phthalates[3] and inositols[4], whereas a predominance of inversion occurs in the liquid octanols and inositol ethers[5] and in simple amino-acids[6]. In the catalytic technique, results from the only heavy-water system studied show that, in optically active lactic acid, deuteration of the α-position is generally accompanied by inversion[7].

For biological purposes, the labelling of amino-acids, particularly phenylalanine, in one step with retention of configuration, could be valuable. During charge-transfer mechanism studies of catalytic exchange with isotopic water[6], it has been observed that appreciable isotope incorporation only occurs if a compound contains a double bond or an aromatic ring. In simple amino-acids, such as alanine, it would be expected that catalytic exchange with D_2O would be low, as the system is essentially aliphatic in nature. However, by analogy with lactic acid, if the electron lone-pair on the nitrogen assists the absorption process and thus increases the exchange, isotope incorporation may occur predominantly by inversion since the asymmetric centre would be in close proximity to the catalyst surface. In phenylalanine, it is possible for the molecule to be π-complexed to the catalyst surface through the aromatic ring[8] and thus be highly deuterated without inversion of configuration. In addition to the biological implications, such a result would be further evidence to support the π-complex theory of catalysis[9].

For the present investigations, alanine, phenylalanine and mandelic acid have been exchanged with D_2O in the presence of hydrogen pre-reduced platinum, since platinum is the most active of the Group VIII transition metals for exchange[10]. In a typical experiment, L(−)-phenylalanine (0·4 g) in D_2O (5·5 g) was heated to 130° C with pre-reduced platinic dioxide (0·02 g) for 48 h. After purification of the deuterated compound, deuterium analyses were performed on a Metropolitan–Vickers *MS–2G* mass spectrometer and a Varian *A*-60 nuclear magnetic resonance spectrometer.

mechanism of exchange probably involves two competing dissociative mechanisms as previously discussed for the alkyl benzenes[8,11]. The relatively high isotope incorporation in the ring suggests that aromatic exchange again occurs predominantly by the dissociative π-complex substitution mechanism[12].

Lack of deuteration and inversion at the tertiary carbon atom of phenylalanine during the low-temperature exchange indicates that the molecule is tilted during adsorption so that the proton at this position never touches the catalyst surface (as in (I)). This effect has already been discussed during the catalytic exchange of the alkyl benzenes[8]. As the temperature of exchange is increased from 30° to 130° C, it is obvious that the effect of the second competing dissociative exchange reaction increases.

(I) (II)

The results with mandelic acid (adsorbed as in (II)) are consistent with the phenylalanine data. The only hydrogen in the α-position in mandelic acid is adjacent to the aromatic ring and attached to a tertiary carbon atom. Thus, it is not surprising to find that some inversion

¶ and ‖ Percentage approach to statistical equilibrium for *d*- and *l*-isomers of mandelic acid respectively.

From the results given in Table 1, alanine exchanges very slightly at room temperature but deuterates extensively with appreciable inversion of configuration at 130° C, thus indicating that the lone-pair on the nitrogen may assist the adsorption process. This is confirmed by a study of the nuclear magnetic resonance of the distribution of isotope in the alanine deuterated at 130° C, since 47 per cent of the hydrogen at the asymmetric carbon atom is replaced by deuterium while only 30 per cent deuteration of the methyl hydrogen occurs.

The significant feature of the present results is that L(−)-phenylalanine readily exchanges at 130° C with a predominance of inversion of configuration whereas, after shaking for three days at 30° C, deuteration is still relatively efficient with retention of configuration. Distribution of the isotope in the labelled phenylalanine from the latter reaction shows that deuteration has occurred essentially in the phenyl group with no observed isotope at the asymmetric carbon atom. This would indicate that the occurs with deuteration, even at 30° C. At the higher temperature, however, interpretation is difficult because of a thermal-induced inversion of configuration which occurs without catalyst.

For biological reactions involving labelled phenylalanine, the present result is significant since, with D_2O and moderate activity-levels of T_2O, the catalytic procedure can be used, at room temperature, to tag optically phenylalanine with retention of configuration. However, care should be exercised in extrapolation of the technique to high levels of T_2O (c./ml.) since an additional radiation-induced activation of the reaction would be expected[13], with possible consequential changes in stereochemical configuration[6,14]. The present results are important since they should act as a general guide to the type of results to be expected during the catalytic tritiation and deuteration of all amino-acids.

Stereospecific Addition of Hydrogen to Fumaric Acid in Irradiated Single Crystals of Succinic Acid

Pooley and Whiffen[1] reported an interesting proton–deuteron exchange reaction of the primary radical $HOOCCH_\beta H_{\beta'}CH^{\alpha}COOH$ (or $DOOCCH_\beta H_{\beta'}CH_\alpha COOD$)[2] in an irradiated crystal of succinic acid. By means of an electron spin resonance technique, they detected $DOOCCD_\beta H_{\beta'}CHCOOD$ in addition to the primary species, but they did not detect $DOOCCH_\beta D_{\beta'}CHCOOD$, nor $DOOCCH_2CDCOOD$ (hyperfine splitting constant for H_β is larger than that for $H_{\beta'}$[2]). It was shown later[3,4], however, that formation of this $DOOCCD_\beta H_{\beta'}CHCOOD$ species is associated with an unidentified impurity in the crystal; the impurity is too low in concentration to be detected with ordinary experimental techniques. During the present investigation it was found that fumaric acid behaved quite similarly to the impurity: in a crystal of succinic acid which contained 0·001 mole fraction of fumaric acid, the ratio

$$[DOOCD_\beta H_{\beta'}CHCOOD]/[DOOCCH_2CHCOOD]$$

was found to be 0·2, that is, the same as the ratio found in the impure crystal[3].

The crystals used in this investigation were grown by slowly cooling aqueous solutions of mixtures of succinic acid and fumaric acid. Heavy water was used for the deuterium-substituted crystals. Concentrations of fumaric acid in the crystals were estimated from those of their mother liquors. The relation between the concentration of fumaric acid in the crystal and that in its mother liquor was determined by means of radioactive fumaric acid HOOCC*H = C*HCOOH. Irradiation of the crystals was accomplished by an X-ray source (30 kV, 15 m.amp) at room temperature, and the concentration of the radicals was about 7×10^{-4} radical/molecule. The electron spin resonance absorption was measured at 9 Gc/s at room temperature.

In any crystals which were grown from the aqueous solutions, only the primary species was detected. In the deuterium substituted crystal, which contained more than a 0·0001 mole fraction of fumaric acid, the $DOOCCD_\beta H_{\beta'}$-CHCOOD species was detected, in addition to the primary species. When 2,3-deuterofumaric acid was used, the absorption from $DOOCCD_2CDCOOD$ replaced this absorption. Thus, it was concluded that the radical $DOOCCD_\beta H_{\beta'}CHCOOD$ was formed by addition of hydrogen (deuterium) to fumaric acid.

Concentration of $DOOCCD_\beta H_{\beta'}CHCOOD$ increased with increasing concentration of fumaric acid in the crystal, until the latter concentration became about 0·01 mole fraction. For the crystal in which the concentration of fumaric acid was higher than 0·01, ratio

$$[DOOCCD_\beta H_{\beta'}CHCOOD]/[DOOCCH_2CHCOOD]$$

was found to be about 0·65.

From the signal-to-noise ratio of the absorption pattern of the crystal, the ratio

$$[DOOCCH_\beta D_{\beta'}CHCOOD]/[DOOCCD_\beta H_{\beta'}CHCOOD]$$

was found to be less than 1/300. In an isolated molecule of fumaric acid, these two species should have been formed with an equal reaction rate. Therefore, there was no uncertainty that this large difference in the addition rates arose from the crystal field which surrounded the molecule of fumaric acid. Such an effect of the crystal field on a chemical reaction had already been reported in the case of proton–deuteron exchange reaction of the radical in irradiated crystals of D,L-aspartic acid[4,5].

So far as we know, a high stereospecific efficiency, such as that observed at present, has been found only in the case of enzymatic reactions[6]. Moreover, it is well known that an enzyme is highly selective in its reactions. Such high selectivity was also found in the present case. So far as our examination was concerned, fumaric acid was the only compound from which a radical was formed with the use of an irradiated crystal of succinic acid. The other compounds examined (inactive compounds), which are more or less similar to fumaric acid in structure, were as follows: maleic acid, oxalic acid, crotonic acid, acrylic acid, tartaric acid, and D,L-aspartic acid. It was not known, however, whether a crystal, grown from a solution containing one of the inactive compounds in addition to succinic acid, contained a significant concentration of molecules of this compound.

We thank Prof. W. Gordy for his advice, and Prof. N. Tamiya for supplying 2,3-deuterofumaric acid.

Anomalies in Contact Angle Behaviour for Ethyl Alcohol–Water Mixtures

Measurements of static contact angles for alcohol/water mixtures on pretreated copper surfaces are presented in Fig. 1. The results indicate that, for ethyl alcohol concentrations up to 8 per cent by weight, a constant contact angle of 72° is attained. Analogous behaviour has been observed by Franke[1] when measuring mutual diffusivities where a minimum value was reported at 10 per cent concentration. Hoffman *et al.*[2] have shown a maximum value of the temperature coefficient of the surface tension of ethyl alcohol/water mixtures at 8 per cent weight.

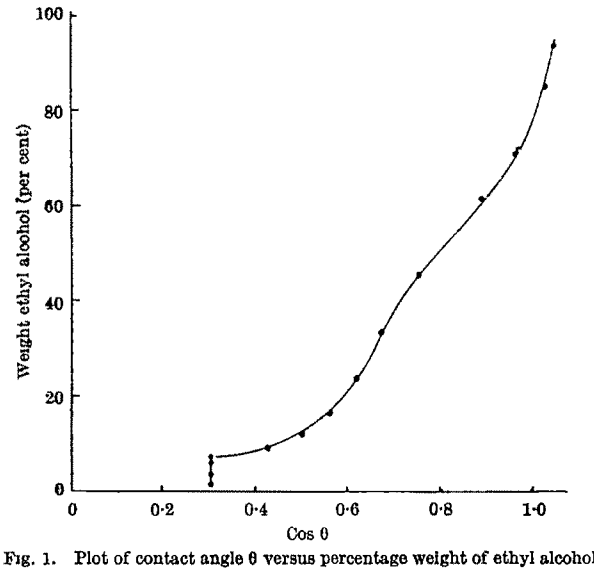

Fig. 1. Plot of contact angle θ versus percentage weight of ethyl alcohol

This behaviour again demonstrates the anomalous bulk and surface properties of dilute alcohol/water mixtures.

BIOCHEMISTRY

Impaired Ability of Ribosomes to react with Polyuridylic Acid after Hypophysectomy of the Rat: Removal of the Disability by a Cell Sap Factor

The liver ribosomes of hypophysectomized rats are less able to incorporate amino-acids into protein *in vitro* than those of normal rat liver[1]. Ribosomal preparations from hypophysectomized rats contain less polysomes than those from normal rats[2], and the rate of synthesis of messenger ribonucleic acid (*m*RNA) and other kinds of RNA is depressed[2,3] after hypophysectomy. The action of growth hormone in promoting protein synthesis and growth can be explained in terms of its action in stimulating the synthesis of *m*RNA[2,4], but this hypothesis does not explain all the facts. It has been noted[4], for example, that the percentage stimulation of phenylalanine incorporation obtained by addition of 25 μg of polyuridylic acid (poly U) to the cell-free system with ribosomes from liver of hypophysectomized rats was as great as, or greater than, that obtained when ribosomes from liver of normal rats were used; but the absolute level of incorporation with ribosomes from hypophysectomized rats was still less than that obtained with normal rat liver ribosomes. The amount of poly U used was arbitrary and was probably not optimal for the system; thus it was decided to reinvestigate this point under conditions which were optimal for incorporation of phenylalanine into polypeptide in the presence of poly U.

The total ribonucleoprotein particle population of the sodium deoxycholate-treated, 10,000*g* supernatant material of liver homogenate was prepared by centrifugation at 100,000*g* for 4 h over 1 M-sucrose containing medium *M* (0·02 M *tris* buffer, *p*H 7·5, 100 mM potassium chloride, 40 mM sodium chloride, 10 mM magnesium acetate and 6 mM mercaptoethanol) as previously described[2,5]. The optimum conditions for incorporation of amino-acids had already been elucidated[5]. Two, which are not widely observed, are to treat the cell sap with 'Sephadex' to remove inhibitors and to use at least 20 times as much sap protein as ribosome protein to ensure that sap factors are not limiting[5]. Observing these conditions, the amount of poly U which was necessary to saturate the system was determined. It was found that incorporation of phenylalanine rose rapidly with increasing amounts of poly U, came to a plateau when the amount of poly U added was about ten times the concentration of ribosomal RNA, but thereafter continued to rise very slowly. In subsequent experiments, ribosomes containing 10 μg RNA were incubated with 250 μg poly U in medium *M* with 5 mM ATP, 0·6 mM guanosine triphosphate and 0·3 μc. D,L (3-^{14}C) phenylalanine (34 mc./mmole) and various amounts of 'Sephadex'-treated cell sap. The radioactive protein was prepared and counted in a manner previously described[5].

Table 1 shows typical results. It will be seen (lines 1 and 2) that even when saturating amounts of both cell sap and poly U are present, the incorporation of phenylalanine into polypeptide with ribosomes of hypophysectomized rat liver is much less than that obtained with ribosomes from normal rat liver. This result, which has been repeatedly obtained, must mean that hypophysectomy of the rat impaired the ability of liver ribosomes to react with poly U to form an active polysome. It gives experimental support to the argument, previously expressed[4,6,7], that stimulation of protein synthesis by growth hormone cannot be explained simply and entirely in terms of altered rates of *m*RNA synthesis; other factors are involved. Similar results have been obtained with heart ribosomes of the rat[8] and with muscle ribosomes of alloxan-diabetic and insulin-treated rats[9].

Table 1. Stimulation of the Incorporation of Phenylalanine by Poly U with Liver Ribosomes from Normal and Hypophysectomized Rats

Amount of cell sap protein per unit of ribosomal RNA	C.p.m./μg ribosomal RNA: Normal rat ribosomes		Hypophysectomized rat ribosomes	
	No poly U	Poly U (250 μg)	No poly U	Poly U (250 μg)
20	960	10,300	560	4,800
50	1,700	13,800	750	7,300
100	1,200	21,500	860	12,800
200	1,270	33,000	970	26,500
400	1,910	26,500	1,310	25,800
800	2,300	19,000	1,570	18,600
1,000	2,560	12,000	1,850	11,500

The amount of cell sap required to saturate the ribosomes had been calculated from experiments carried out in the absence of poly U[5]. It seemed possible that more sap might be required for saturation when large amounts of poly U are present. Ribosomes were incubated, with or without poly U, in the presence of large quantities of cell sap. Saturation was achieved with a twenty-fold excess of sap to ribosomes[5], but in the experiments summarized in Table 1 up to a thousand-fold excess was studied. Three interesting observations emerged. (1) In the absence or presence of poly U, increasing the sap concentration above the 'saturating' level resulted in increased incorporation. This was not caused by ribosomal contamination of the cell sap, for incubation of it without ribosomes resulted in little incorporation and no particles could be detected when cell sap was studied in a Spinco model *E* analytical ultracentrifuge. (2) In the presence of poly U, but not in its absence, concentrations of sap greater than about 200 times that of the ribosomes had an inhibitory effect. (3) In the presence of poly U when the cell sap concentration reached 200–400 times that of ribosomes, the difference in incorporation of phenylalanine with ribosomes from normal and hypophysectomized rats disappeared. Cell sap contains a factor other than the amino-acid activating enzymes and *s*RNA necessary for maximum incorporation of phenylalanine in the presence of poly U; this factor is required to a greater extent by ribosomes from liver of hypo-

physectomized rats than by ribosomes from normal rat liver.

Bacterial Degradation of Glycoprotein Sugars in Human Saliva

Previous reports[1,2] have indicated that sialic acid in human, wax-stimulated saliva is rapidly released and metabolized by the oral flora. Heat (100°, 5 min), or antibiotic, prevents both these reactions from taking place. Further investigations have now shown that the other sugars associated with the salivary glycoproteins (3 hexoses, 2 hexosamines and fucose) are all spontaneously lost from saliva by bacterial action, and this loss may also be prevented by either heat or antibiotics. Wax-stimulated saliva contains, with the exception of fucose, all these sugars in two distinct forms: those in the salivary glycoproteins and those in the many and varied bacteria (10^8/ml.) also present in the saliva. Many of the bacteria in the saliva contain rhamnose, a 6-deoxyhexose of the same group of sugars as fucose, but it is possible to distinguish between these two sugars by either paper or thin-layer chromatography[3]. By this method it was shown that the 6-deoxyhexoses in freshly collected, wax-stimulated saliva consisted of rhamnose and fucose. It was also shown that, on incubation, the saliva rapidly lost all its fucose and sialic acid, while the rhamnose remained. The hexoses and hexosamines, however, occurred in the salivary glycoproteins and the bacteria, and it was not possible to distinguish between these sources by direct analysis or by chromatography. On incubating wax-stimulated saliva, 50–70 per cent of the hexoses and hexosamines were lost, but it was not possible in this instance to distinguish whether the remaining sugar was derived from the salivary glycoproteins or from the bacteria. If the saliva was collected directly from the salivary ducts (parotid, submaxillary and sublingual) and pooled, there were now present so few bacteria that all the sugars from the glycoproteins remained intact on incubation and the saliva remained clear and viscous. The addition of bacteria, in the form of dental plaque or salivary sediment, to the viscous duct saliva caused a rapid loss of sugars, a drop in viscosity and the formation of a precipitate. After incubation no fucose or sialic acid was present and the amount of residual sugars was approximately equal to that from the added bacteria. In none of the experiments described here has it been possible to detect any but traces of free sugars in the saliva when bacteria have been present, and these sugars were also rapidly metabolized when added in a free state to the saliva. It is thus apparent that the carbohydrate components of the glycoproteins in saliva are labile in the oral environment and are rapidly released and metabolized by bacterial action. The loss of these sugars, particularly sialic acid, provides an explanation for the observed drop in viscosity and formation of a precipitate that occurs spontaneously in wax-stimulated saliva[1,2]. Previous suggestions that the drop in viscosity is due to a mucinolytic depolymerization of the salivary glycoproteins[4] are valid so far as the viscosity-drop is concerned, but this mechanism should produce a product of increased solubility, and, in fact, a heavy precipitate always appears concomitantly with the drop in viscosity. It is tempting to postulate that this is the mechanism whereby the material from the saliva forms a matrix holding together the many bacteria adjacent to the teeth, which is commonly referred to as dental plaque. Support for this is found in the observation that dental plaque is practically devoid of both sialic acid and fucose ($<0{\cdot}002$ per cent), the two essential sugar constituents of salivary glycoproteins that can be identified as belonging exclusively to the glycoproteins and not to the oral bacteria.

We thank Miss C. Jackson and Mr. P. Van der Zeil for their help.

High Content of Hyaluronic Acid in Normal Human Heart Valves

During the course of investigations of the effect of age on acid mucopolysaccharide content of the human heart valves, we found hyaluronic acid to be a major component. In all it represented about 60 per cent of the acid mucopolysaccharide present in the tissue. This observation is in striking contrast with reports from other laboratories[1,2] which have shown hyaluronic acid to be a minor component of both bovine and pig heart valves. This communication reports the distribution of the acid mucopolysaccharide fractions of the normal human heart valves.

For total acid mucopolysaccharide determination, individual heart valves (approximately 50 mg) were dried, de-fatted and subjected to papain digestion and the protein separated by precipitation with trichloroacetic acid. The acid mucopolysaccharide is precipitated by cetylpyridinium chloride, dissolved in sodium chloride and reprecipitated with ethanol. For fractionation, extracted acid mucopolysaccharide of about ten valves of the same age-group was pooled. The acid mucopolysaccharide was fractionated to hyaluronic acid, chondroitin sulphuric acids and heparin according to Schiller *et al.*[3]. Applying this method, hyaluronic acid, chondroitin sulphates, and heparin were obtained at 0·4 M, 1·2 M, 2·1 M sodium chloride solution, respectively. Chondroitin sulphate *B* was further separated from chondroitin sulphate *A* or *C* by hyaluronidase (testicular) digestion. The total acid mucopolysaccharide is expressed as uronic acid and determined by the carbazole reaction[4]. The results of such a fractionation procedure are shown in Table 1. The total acid mucopolysaccharide present in the mitral heart valve is 0·93 mg uronic acid/100 mg dry weight and is significantly higher than in the tricuspid valve ($P < 0{\cdot}01$ analyses were carried out on fourteen individual valves). In both valves there is no change in the distribution of various fractions of acid mucopolysaccharide and it can be seen that hyaluronic acid represents 58 per cent

Table 1. Total Acid Mucopolysaccharide (AMPS) Content and Individual AMPS Fractions from Human Heart Valves

Heart valves*	Total AMPS†	Fraction (per cent) HA	CSA—*A*/*C*	CSA—*B*	Heparin
Mitral	0·93	58·8	27·3	13·6	Trace
Tricuspid	0·74	57·7	28 0	14·3	Trace

HA, hyaluronic acid; CSA—*A*/*C*; chondroitin sulphate *A* or *C*; CSA—*B* chondroitin sulphate *B*.
* These heart valves were obtained from subjects of 20–30 years of age.
† Mg of uronic acid/100 mg dry de-fatted valve.

of the total acid mucopolysaccharide present. Chondroitin sulphate *A* or *C* is about 28 per cent while chondroitin sulphate *B* is 14 per cent. The actual amount of chondroitin sulphate *B* is a little higher than this value because of the low carbazole value of iduronic acid in chondroitin sulphate *B*. Trace amounts of acid mucopolysaccharide were found in the 2·1 M sodium chloride fraction (heparin) but the attempt to identify this fraction as heparin was not successful. Paper chromatography[5] of acid hydrolysed fraction showed spots corresponding to glucosamine in the 0·4 M sodium chloride fraction and galactosamine in the 1·2 M sodium chloride fraction. This confirms the presence of hyaluronic acid only in the 0·4 M sodium chloride fraction and rules out any contamination of chondroitin sulphates into this fraction and also the presence of chondroitin (chondroitin and chondroitin sulphates contain galactosamine). Similarly the 1·2 M sodium chloride fraction had chondroitin sulphates and not heparitin monosulphate (heparitin monosulphate contains glucosamine). The significance of the difference in hyaluronic acid content of human and animal heart valves is not clear. Further investigations are in progress which are aimed at elucidating the relationship of this high content of hyaluronic acid in human heart valve with function.

We thank Dr. A. Angrist for his interest and encouragement in this work. This work was supported by grants from the U.S. Public Health Service, *HE*–02190–09.

K88, an Episome-determined Protein Antigen of *Escherichia coli*

Recently, I. Ørskov, F. Ørskov, W. J. Sojka and J. M. Leach[1] described a new genetical donor strain of *Escherichia coli*. This strain, *G7* (O8 : K87(B) : K88ab(L) : H19), was at first isolated from a case of pig enteritis. Investigations in different countries have shown that this serotype is frequently found in enteric diseases in pigs. A characteristic feature was the simultaneous existence of two K antigens in the same strain. The K87(B) antigen is a polysaccharide as are all hitherto examined B (and A) antigens[2]. The K88 antigen is thermolabile, that is, its ability to agglutinate and to bind antibody and its capacity to induce antibody formation in rabbits are destroyed by heating to 100° C for 1 h and thus it must be grouped as an L antigen according to established definitions[3]. Since the first detection of the K88 antigen it has been found in many *E. coli* strains, mainly from young pigs with intestinal diseases, and in different serological combinations[4–6]. Furthermore, it has been shown that K88 exists in at least two varieties, one of which is symbolized as K88ab, and the other K88ac (ref. 4). Strain *G7* is a genetical donor and can, in conjugation experiments, transfer chromosomal markers to suitable recipients. In addition the genetic determinant of the K88 antigen can be passed to other *E. coli* serotypes by episomal transfer[7].

When *E. coli* cultures, collected from beef broth agar plates, are suspended in saline, considerable amounts of the surface antigens are released into solution. By gentle heating the amounts of released antigens can be increased considerably.

In order to isolate the K88 from such an extract containing as few other contaminating antigens as possible, the K88 factor was transferred to *D*282 (O8 : K27(A)$^-$: H$^-$, lac$^+$), a strain that carried no K and no H antigen. An overnight broth culture of *D*282 (0·003 ml.) and 0·3 ml. of a broth culture of donor strain *D*432 (O8 : K87(B) : K88(L) : H19, lac$^-$) were inoculated together in 50 ml. broth and incubated overnight at 37° C. The mixed culture was spread on bromothymol blue lactose plates and after incubation lactose-positive colonies (*D*282) were tested for K88 by slide agglutination. About 15 per cent of the lactose-positive colonies had acquired the K88 antigen. One such clone (*D*520) was purified and used for the production of K88 antigenic material. Apart from the acquisition of K88, *D*520 had all fermentation and antigenic markers of the *D*282 parent.

For production of K88 antigenic material, *D*520 was heavily inoculated on to thick broth agar plates (14 cm diameter) which were incubated for about 20 h at 37° C. The confluent surface growth was scraped off into *p*H 7–8, 0·1 molar phosphate buffer, 3–5 ml. buffer per plate, and the suspension was then heated for 20 min at 60°–65° C in a water-bath and finally centrifuged at 10,000 r.p.m. for 10 min. The supernatant was stored for at least 3 days at 4° C. During this time some impurities separated out and centrifugation was then repeated and followed by filtration through a 0·65μ 'Millipore' filter. Sterility was ensured by addition of 0·01 per cent 'Merthiolate'. Since it was observed that the K88 antigenic material was soluble in buffers of *p*H < 3·5 (partial denaturation) or > 6·5, but completely insoluble between *p*H 4·5 and 5·5, dilute acetic acid was added to bring the *p*H to the isoelectric region. The precipitated material was collected by centrifugation and washed twice with a *p*H 5, 0·005 molar McIlvaine buffer. For purification, the product was repeatedly redissolved in *p*H 7, 0·01 molar phosphate buffer by gentle stirring in the cold, filtered as already described, and precipitated again by addition of approximately the same volume of *p*H 4·8–5·0, 0·15 molar McIlvaine buffer. As determined by the biuret reaction, approximately 2 mg of K88 antigen was thus obtained from one plate.

Extraction and purification of the K88 antigen were controlled by a filter paper disk modification of the Ouchterlony gel-precipitation technique. Filter paper disks 6 mm in diameter, as used for sensitivity tests, were saturated with either bacterial agar plate culture (by placing them directly on the confluent growth), with bacterial extracts or with different K88 preparations and then placed on a 2 mm agar layer in a Petri dish. Antisera (mostly undiluted) were applied in the same way. K88, purified by repeated isoelectric precipitation, showed but one precipitation line against *D*520 rabbit serum (Fig. 1). The material sedimented uniformly in the analytical ultracentrifuge—a small contamination by some heavier component could be removed by short (15 min) centrifugation at 40,000 r.p.m. The K88 agglutinins could be selectively removed from the homologous OK serum by absorption with the purified K88 antigen.

As shown by the disappearance of the K88 line in the Ouchterlony test, the antigen is denatured by heating to above 70° C or by treatment with mineral acid, sodium

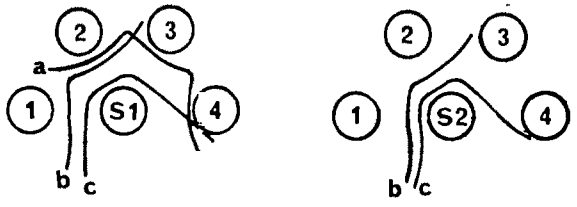

Fig. 1. Gel precipitation using purified K88 antigen, bacterial extracts of strains with and without K88 antigen and sera against such strains. Bacterial extracts: (1) *D*282 (O8 · K27$^-$: H$^-$); (2) *D*520 (O8 : K27$^-$: K88 : H$^-$); (3) *D*214 (O1(1) · K(B) : K88 : H2); (4) Purified K88 antigen. Sera: S1, OK antiserum *D*520; S2, OK antiserum *D*282. Precipitation lines: *a*, K88 line; *b*, lipopolysaccharide line (O antigen); *c*, non-specific, common antigen

hydroxide solution or formamide in the cold. The K88 precipitation line is stained by amido black but not by lipoprotein stains such as oil red or Sudan black[8]. The effect of proteinases on the material was investigated in the following manner: K88 antigen (six parts) in *p*H 7, 0·1 molar phosphate buffer was digested with crystalline trypsin (1 part)[9] at 28°–30° C. After various reaction times, the trypsin was inactivated by addition of soy-bean inhibitor (two parts)[9] and the mixture compared by agar-gel diffusion with undigested K88, using OK antiserum *D*520. Under similar conditions α-chymotrypsin, *B. subtilis* proteinases, papain and *Streptomyces griseus* proteinase (pronase)[9,10] were applied. Extensive splitting and weakening of the K88 precipitation line indicated that the antigen was affected by *B. subtilis* proteinases, papain, pronase and, to a lesser degree, by α-chymotrypsin. Trypsin had no visible effect.

Solutions of repeatedly precipitated K88 antigen were dialysed exhaustively against distilled water and freeze-dried. The biuret reaction gave nearly 100 per cent protein using bovine serum albumin as a standard and the ninhydrin method for proteins[11] yielded an extinction of 0·015/μg nitrogen/2·6 ml. in a 1 cm cell. The orcinol and indol reactions[11] gave 1·5–3 per cent carbohydrates with glucose as a standard, and the elemental analysis yielded 14 per cent nitrogen and 0·1 per cent phosphorus.

The ultra-violet absorption curve of K88 antigen in 0·1 N sodium hydroxide showed the broad absorption band at about 280 mμ, which is characteristic for proteins, and no shoulder at 260 mμ (nucleic acids).

Bacteria carrying the K88 antigen were also directly treated with proteinases and tested for loss of the antigen by slide agglutination. Whereas digestion with papain soon caused autoagglutinability of the organisms, pronase did not have this effect, but removed the antigen as expected. Treatment with 50 per cent aqueous urea had the same effect.

Solubility in Phenol of Aortic Polysaccharide–Protein Complexes

Buddecke[1] has reported a successful separation of glycoprotein from glycosaminoglycuronoglycan in papain digests of aortic tissue by extraction with 90–95 per cent w/w phenol[2]. This result prompted us to attempt a fractionation, by this method, of the glycoproteins from the glycosaminoglycuronoglycan protein complexes present in material obtained from aqueous extracts of aortic intima.

An extract was prepared by homogenizing finely minced aortic intima in distilled water, stirring slowly for several days and dialysing. Insoluble material was removed by centrifuging and a crude mixture of the polysaccharide–protein complexes was precipitated with ethanol in the presence of potassium acetate. The precipitate was dissolved in water, dialysed, centrifuged and reprecipitated as before. The sediment was washed with ethanol, diethyl ether and air dried.

This material was then extracted with phenol[2]. Determinations of sialic acid (as *N*-acetyl neuraminic acid)[3], uronic acid (as glucuronic acid)[4] and hexosamine (as glucosamine)[5] were used to define the distribution of material. Samples of chondroitin 4-sulphate and chondroitin 4-sulphate protein complex from nasal septum and a crude glycoprotein mixture from pig aorta[6] were included. The results are shown in Table 1.

In view of the observed insolubility in phenol of chondroitin 4-sulphate, chondroitin 4-sulphate protein complex (Table 1) and aorta chondroitin 6-sulphate[1,7], and the reported solubility of aorta glycoprotein in this solvent, a successful separation of these two groups of components should be possible. The results show an almost equal distribution of material between the phenol-soluble and phenol-insoluble fractions. When similar preparations were fractionated with ammonium sulphate[6], the product obtained at full saturation contained mostly phenol-soluble material (Table 1, row 4).

Table 1. Distribution of Sialic Acid, Uronic Acid and Hexosamine between Phenol-soluble and Phenol-insoluble Fractions

Sample		Sialic acid	Uronic acid	Hexosamine
(1) Chondroitin 4-sulphate	Phenol-soluble	—	<1	<1
	Phenol-insoluble		>99	>99
(2) Chondroitin 4-sulphate protein complex	Phenol-soluble	—	<1	<1
	Phenol-insoluble	—	>99	>99
(3) Aqueous aorta extract	Phenol-soluble	38	51	54
	Phenol-insoluble	62	49	46
(4) Crude glycoprotein mixture (ref. 6)	Phenol-soluble	94	87	92
	Phenol-insoluble	6	13	8

Results are expressed as percentages of the total amount in both fractions. Analytical values (expressed as g/100 g material) for samples (1)–(4) were respectively: sialic acid, 0·1, 0 8, 2, 4; uronic acid, 33, 28, 6, 4; hexosamine, 28, 28, 7, 9.

As the glycoprotein components of aorta are usually characterized by the presence of significant amounts of sialic acid and the absence of uronic acid[6] and the glycosaminoglycuronoglycan protein complexes are characterized by relatively large amounts of uronic acid with little or no sialic acid[1,7,8], we conclude that no significant separation of glycoprotein from glycosaminoglycuronoglycan protein complex has been obtained by the use of phenol, and that both types of polysaccharide–protein complex contain phenol-soluble and phenol-insoluble components. These findings are at variance with those of Buddecke[1], who found no phenol-insoluble glycoprotein and no phenol-soluble glycosaminoglycuronoglycan. These differences may be explained in terms of the relative complexity of the aqueous extract where the components are present in forms which may approximate to their native state and where interactions between the various molecular species may occur, thus modifying the properties of the individual molecules. Enzymatic digestion[1], while simplifying the subsequent experimental procedures, is known to modify the polysaccharide–protein structures and this might lead to the observed differences in solubility properties.

Stimulation of Protein Synthesis of Frog Embryo Cells by Larval and Adult Frog Liver Ribonucleic Acid Preparations

RECENT work from our laboratory has characterized certain quantitative properties of DNA and chromatin from developing frog embryos in terms of RNA-polymerase-mediated RNA synthesis[1,2]. Apart from knowing how much RNA can be synthesized using chromatin or DNA as a primer, it would be of interest to know some of the qualitative properties of the RNA synthesized. The present investigation examines two questions: Can added RNA stimulate protein synthesis of intact frog embryo cells? If it can, is this stimulation due to species of tissue-specific RNA molecules directing the synthesis of the appropriate proteins? Liver RNA preparations can stimulate haemin synthesis of minced frog embryos[3] or mouse ascites tumour cells[4], and Niu *et al.*[5] have claimed that liver RNA induces the synthesis of liver specific proteins in ascites tumour cells.

Groups of 25 or 30 early gastrulae of *Rana pipiens*, stage 10 of Shumway[6], were removed surgically from their jelly and membranes, and each was cut into four or eight equal-sized fragments in sterile Niu–Twitty saline medium[7]. The fragments from each group of gastrulae were cultured for periods of 24–50 h at 18° C in 1·5 ml. of Niu–Twitty saline, which contained an RNase inhibitor, polyvinylsulphate, at a concentration of 10 μg/ml. Carbon-14 labelled amino-acids of an algal hydrolysate or ^{14}C-phenylalanine were added to the cultures at levels of 0·5 or 1·0 μc./ml. RNA was prepared by the cold phenol method of Brown and Littna[8] and in some cases the interphases of these extractions were further extracted with phenol at 60° C (ref. 9). In one experiment, RNA was generated from frog liver DNA with *Micrococcus lysodeikticus* RNA polymerase in a cell-free system[1]. The RNA preparations were dialysed against Niu–Twitty medium and the RNA concentration estimated by the orcinol reaction[10]. RNA was added to the cultures at a concentration of 1 mg/ml. At the termination of the period of culture the explants were washed several times with 0·7 per cent sodium chloride and homogenized in this medium. The homogenates were then precipitated with cold 5 per cent trichloroacetic acid (TCA) and washed with 1–4 alcohol–ether. They were then treated with 5 per cent TCA at 90° C for 20 min, and washed with 5 per cent TCA and ether. These final centrifugal residues were dissolved in formic acid, and the pigment granules removed by centrifugation at 10,000*g*. The supernatants were plated and counted with a thin-window proportional counter. All homogenizations, dialyses and centrifugations were performed at 4° C.

In order to obtain anti-haemoglobin sera, blood was collected from the hearts of adult frogs. The red blood cells were washed by centrifugation with 0·7 per cent sodium chloride and haemoglobin was prepared by the method of Drabkin[11]. Anti-haemoglobin sera were obtained by injecting two rabbits subcutaneously three times a week during three alternate weeks with a mixture of equal parts of a haemoglobin preparation (2 per cent protein) and Freund's adjuvant. The rabbits were bled 1 week after the final injection. The reaction of the antiserum with a preparation of haemoglobin, frog serum, and centrifugal supernatants (10,000*g*) of adult frog livers, kidneys or brains revealed only one antigen–antibody precipitate line in agar-diffusion tests[12]. The one reacting antigen in centrifugal supernatants from the organs is haemoglobin from the blood cells in the organs, as the precipitate lines showed reactions of identity with the precipitation line of the haemoglobin preparation. The antiserum appeared to be specific for haemoglobin.

In the experiment designed to test for the synthesis of the globin portion of haemoglobin, centrifugal supernatants (10,000*g*) were obtained from the minced gastrulae cultured with ^{14}C-amino-acids, with or without added RNA. After washing the cultures four times with 0·9 per cent sodium chloride, the tissues were homogenized with 1 ml. of 0·9 per cent sodium chloride. One ml. of anti-haemoglobin serum was added to 1 ml. of centrifugal supernatant from each culture in 2 ml. plastic centrifuge tubes. These were mixed, placed at 37° C for 1 h and at 6° C for another hour, and centrifuged at 10,000*g*. The centrifugal residues were washed four times with 0·9 per cent sodium chloride by centrifuging at 10,000*g*. These residues were then dissolved in formic acid and counted.

The results of a number of experiments in which RNA prepared from different sources was added to the cultured gastrula fragments is represented in Table 1. Comparisons of incorporation of labelled amino-acids into the protein fraction should be made only for the controls and experimental cultures of each individual experiment since the kind and amount of isotopic compound used and duration of culture varied. Examination of these results shows that RNA isolated from the hot phenol (60° C) extracts of the interphase of cold phenol extracts of frog liver RNA stimulated protein synthesis of the embryonic cells. RNA generated *in vitro* from frog liver DNA and yeast-soluble RNA gave lower levels of stimulation. There was no significant increase of incorporation of labelled amino-acids into the protein fraction when RNA of the 105,000*g* centrifugal residues of stage 18 frog embryos, or calf thymus RNA or ammonium polyuridylate was utilized. The absence of stimulation of ^{14}C-phenylalanine incorporation into the TCA precipitates obtained from gastrula cells cultured with ammonium polyuridylate (1 mg/ml.) runs contrary to the idea of specific stimulation, as polyuridylic acid is known to code for polyphenylalanine synthesis[13].

Table 1. EFFECT OF VARIOUS RNA PREPARATIONS ON PROTEIN SYNTHESIS OF CULTURED FRAGMENTS OF FROG GASTRULAE

Exp. No.	Culture conditions	RNA preparation (1 mg/ml.)	Average c.p.m /mg protein	% stimulation
(1)	24 h; 1 μc./ml. ^{14}C algal hydrolysate	None	3,407	
		Frog liver; hot phenol (60° C) extract of interphase of cold phenol extract	4,960	46
(2)	40 h; 0·5 μc./ml. ^{14}C algal hydrolysate	None	7,170	
		RNA generated from liver DNA–RNA polymerase system	8,452	18
(3)	42 h; 0·5 μc./ml. ^{14}C algal hydrolysate	None	7,602	
		Stage 18 tailbud embryo 105,000*g* centrifugal residue (hot phenol, 60° C, *p*H 8·5 extract)	7,229	—
(4)	50 h; 0·5 μc./ml. ^{14}C algal hydrolysate	None	4,873	
		Calf thymus RNA (Nutritional Biochem. Co.)	4,996	
		Yeast soluble RNA (Cal. Bio. Chem.)	5,547	14
(5)	40 h; 0·5 μc./ml. ^{14}C-phenylalanine	None	7,585	
		Ammonium polyuridate	7,955	

The use of a specific anti-haemoglobin serum to precipitate haemoglobin, as well as molecules with similar combining groups, revealed that RNA isolated from various centrifugal residues of adult frog livers and the livers and kidneys of 50 mm frog larvae can stimulate the incorporation of labelled amino-acids into the proteins precipitated by this antiserum (Table 2). Stimulation of protein synthesis also occurred in the supernatant fractions

Table 2. EFFECT OF ADULT FROG LIVER AND LARVAL LIVER–KIDNEY RNA ON HAEMOGLOBIN SYNTHESIS OF FRAGMENTS OF FROG GASTRULAE CULTURED FOR 50 H

RNA preparations added	Average c.p.m. anti-haemoglobin precipitates	% stimulation	Average c.p.m. anti-haemoglobin supernatant	% stimulation

obtained after the antigen–antibody precipitates were removed by centrifugation. The larval livers and kidneys are known to synthesize haemoglobin[14], but the livers of the adult frog are inactive in this respect and would not be expected to possess 'messenger RNA' for haemoglobin synthesis.

The results of this investigation demonstrated that certain RNA preparations can stimulate protein synthesis of frog embryo cells, but suggest that this is a non-specific effect not related to the action of tissue-specific messenger RNA-molecules.

Metabolism of Glutamic and Aspartic Acids in Whole Rumen Contents

Amino-acids occur at low concentrations in the liquid phase of rumen contents[1,2] as intermediates in the breakdown of dietary proteins and in the production of microbial protein. The metabolism of these amino-acids has been investigated, mainly in washed suspensions of mixed rumen micro-organisms and pure cultures. There is abundant evidence of interaction in the metabolism of the amino-acids by the rumen microflora[3,4]. To obtain meaningful rates of utilization, physiological concentrations of all the amino-acids must be used. We report experiments in which glutamic and aspartic acids uniformly labelled with carbon-14 were added to whole rumen contents in true tracer amounts under conditions closely approaching those in the living animal.

For these experiments a sheep was fed a diet of pelleted dried grass meal continuously from a conveyor belt. The pellets from the machine arrived on average at intervals of 1–2 min, the food being eaten on presentation. Under this régime concentrations of metabolites in the rumen remained constant: in other words, a steady state was maintained. It was thus possible to compare entry rates obtained by the isotope dilution technique with the feeding rate.

Representative samples of uniform size were obtained using the continuous externalized circulation of the rumen content described previously[5] and transferred immediately for incubation at 40° C under nitrogen + carbon dioxide (50 : 50). Experiments were begun by injection of the isotopic amino-acid, and terminated by injection of 0·05 vol. of 10 N sulphuric acid, followed by chilling to 0° C. Samples were centrifuged at 1,500 r.p.m. for 2·5 min and the cloudy supernatant fluid centrifuged at 20,000 r.p.m. for 10 min.

The residue from high-speed centrifugation consisted almost entirely of bacteria and was washed twice with saline containing carrier inert amino-acid. There was little variation in the composition of the rumen content from day to day and the procedure of isolation of this fraction of the bacteria was rigidly standardized so that a constant proportion was collected. This proportion was found in separate experiments in which carbohydrates labelled with carbon-14 were metabolized, the ratio of radioactivity in amino-acids isolated from a hydrolysate of the bacterial fraction and in a hydrolysate of unfractionated contents giving this proportion.

The supernatant fluid from high-speed centrifugation was analysed for radioactivity remaining in the amino-acid and for radioactivity in short-chain fatty acids. Carbon dioxide was collected in parallel experiments and counted as barium carbonate. Amino-acids were separated and estimated as their 2 : 4-dinitrophenyl derivatives[6,7] and the short-chain fatty acids by steam distillation and gas chromatography[8]. Both glutamic acid-U-^{14}C and aspartic acid-U-^{14}C were metabolized rapidly with the incorporation of a great part of their radioactivity into short-chain fatty acids and carbon dioxide. The first phase of the decay curves corresponded to half-lives of 72 and 54 sec and entry rates for the whole rumen of 92 and 98 mmoles per day for glutamic and aspartic acids respectively.

Feeding rates of glutamic and aspartic acid calculated from analysis of hydrolysates of the diet were 80 and 88 mmoles per day. The shape of the decay curves indicates some re-entry of the amino-acid from secondary pools

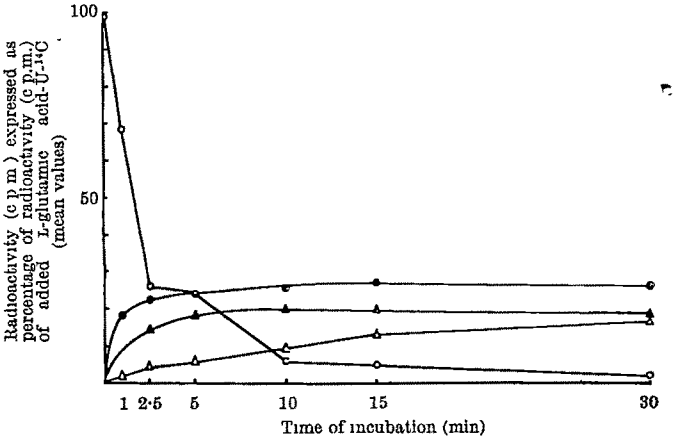

Fig. 1. Time course of the decay of radioactivity of L-glutamic acid-U-^{14}C (○) and the incorporation of radioactivity into short-chain fatty acids (●), carbon dioxide (▲), and bacterial hydrolysate (△) in sheep rumen content *in vitro*

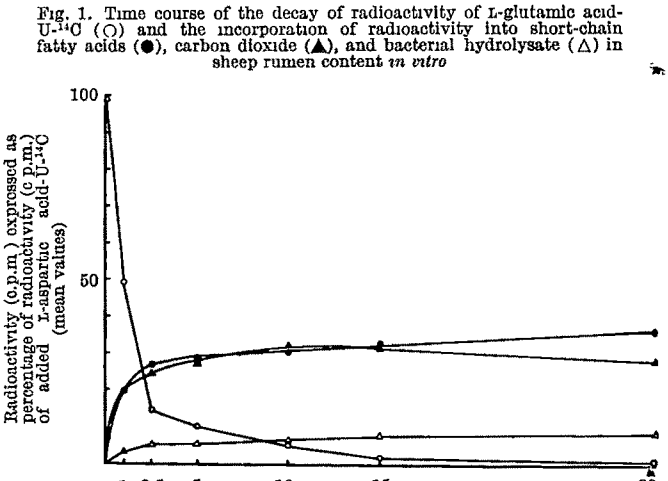

Fig. 2. Time course of the decay of radioactivity of L-aspartic acid-U-^{14}C (○) and the incorporation of radioactivity into short-chain fatty acids (●), carbon dioxide (▲), and bacterial hydrolysate (△) in sheep rumen content *in vitro*

so that entry rates calculated from the initial decay overestimate the rates of production of the amino-acids.

The results, however, leave little doubt of the importance of the free glutamic and aspartic acids of the rumen fluid, the small concentrations observed being a reflexion of their rapid turnover. Some 17 per cent of the radioactivity of glutamic acid could be accounted for in the hydrolysed bacteria. About 10 per cent was as glutamic acid, the rest being mainly in other amino-acids. The corresponding figures for aspartic acid were 8 per cent for total radioactivity in hydrolysed bacteria, about half of which was present as aspartic acid. Net ammonia production was negligible under the conditions examined so that dietary nitrogen metabolized would appear almost quantitatively as microbial nitrogen.

The experiments we have described show that the main fate of glutamic and aspartic acids under physiological conditions in rumen contents is metabolism to carbon dioxide and short-chain fatty acids and that direct incorporation of these amino-acids into bacterial protein is small. Analysis showed glutamic and aspartic acids to occur in high proportion in the bacterial nitrogen. These amino-acids in the microbial protein must come almost exclusively from *de novo* synthesis.

Distribution Patterns of Proteolytic Enzymes in Normal and Leukaemic Human Leucocytes

Proteolysis is a well-known function of leucocytes[1,2], but literature on the distribution of defined proteolytic enzymes in different types of leucocytes is scarce[3–9]. In this investigation, nine peptidases were estimated in normal and leukaemic leucocytes. Four of them (cathepsin carboxypeptidase, leucine aminopeptidase, imidodipeptidase, iminodipeptidase) were demonstrated in leucocytes for the first time.

Leucocytes were isolated using the method of Lohr and Waller[10]. Proteinase activity was measured by the method of Anson[11]. The exopeptidases were estimated by means of quantitative paper chromatography[12]. For details of assays see Table 1. The assays contained 6·5 million (proteinases) and 10·4 million (exopeptidases) cells per ml. on average. The buffer concentration was 0·025 M. With the exception of glycyl-leucine dipeptidase, which was hydrolysed according to second-order kinetics, the velocities were computed on the basis of first-order rate constants.

Some properties of the enzymes deserved special attention. Most peptidases are fully active in a saponin (0·1 per cent w/v) lysate. Neutral proteinase, however, which undergoes a fifteen-fold increase in activity on addition of saponin[3], is activated a further 6 times by subsequent homogenization (5 min in a Potter–Elvehjem-type homogenizer, cooled by iced water). Cathepsin carboxypeptidase, tested on the cells of chronic myeloid leukaemia, is activated 250 per cent by 10 mM L-cystein. The activity of leucine aminopeptidase (substrate: L-leucine amide[13]) is enhanced 230 per cent by 0·2 mM Mn^{2+}, 35 per cent by 1 mM Mg^{2+}, and 16 per cent by 0·2 mM Co^{2+}, whereas the enzyme splitting L-leucyl-β-naphthylamide (LNAase) is not activated by manganese ions[9] and the enzyme cleaving L-leucyl-glycine is activated by traces of Zn^{2+} (ref. 7).

The results are shown in Table 1. Neutral and acid proteinases, aminotripeptidase, and carboxypeptidase appear to be characteristic enzymes of the granulocytic series. Glycyl-glycine and glycyl-leucine dipeptidases are very active in lymphocytes. The greatest differences are shown by neutral proteinase and glycyl-leucine dipeptidase. The low activities of these enzymes in the cells of chronic lymphoid and myeloid leukaemia, respectively, may be due to contamination by granulocytes (10 per cent) in the case of neutral proteinase and by lymphocytes (4 per cent) in the case of glycyl-leucine dipeptidase; in other words, these enzymes may be absent in lymphocytes and granulocytes, respectively.

Compared with granulocytes, most activities in the myeloblasts of acute leukaemia are unchanged or lowered, except for leucine aminopeptidase and prolidase, the activities of which are significantly elevated. In this respect, also, leucine aminopeptidase differs from LNAase, which was reported to be significantly decreased in acute myeloblastic leukaemia[8]. It is evident, therefore, that leucine aminopeptidase and LNAase are two different enzymes.

The cells of the so-called 'myeloblastic' crisis which terminates chronic myeloid leukaemia are, on a morpho-

logical basis, indistinguishable from those of acute myeloblastic leukaemia. Their enzyme pattern, however, is evidently different (especially for neutral proteinase, leucine aminopeptidase, and glycyl-leucine dipeptidase) and cannot be distinguished from that of lymphocytes. The cells of the terminal crisis, therefore, should not be termed myeloblasts. Perhaps they correspond to a more primitive type of cell, which is functionally related to lymphocytes[14,15].

PHYSIOLOGY

Effect of Gonadotrophins on Uterine Growth of Hypophysectomized Mice

It was shown by Lamond and Emmens[1] that the effective dose (*ED*) of human chorionic gonadotrophin (HCG) for uterine growth in intact immature Swiss albino (*S.W.* strain) mice was approximately 0·2 I.U. The *ED* is defined as the amount of gonadotrophin, given in one injection, that will result in uteri weighing approximately 12 mg 44–48 h later (that is, approximate doubling of uterine weight). When the mice were hypophysectomized a few minutes before injection, the *ED* was increased to about 2·0 I.U. However, 5–6 h after hypophysectomy even very large doses of HCG had no effect on uterine weight. We have shown that the time of the day when the mice are hypophysectomized influences the *ED* of HCG when the injection is given at the time of hypophysectomy[2]. The mean *ED* after hypophysectomy at 9–10 a.m. was 3·0 I.U., and after hypophysectomy at 3–4 p.m. was 0·6 I.U.

It is generally accepted that follicle-stimulating hormone (FSH) augments the action of HCG on the ovary. The Steelman–Pohley assay[3], using ovarian weights, is based on this assumption. We have used this phenomenon of augmentation of HCG by FSH for the assay of FSH, but have based our determinations on production of uterine growth-promoting substances produced by the ovary. The standard technique involves hypophysectomy before 10 a.m. followed 5–6 h later by injection of 4·5 I.U. of HCG and the unknown in single subcutaneous injections at separate sites. The mice are killed 44 h after injection and uterine weights recorded. Full details of the assay and certain modifications that should allow its use for routine work have been given elsewhere[2]. The assay is sensitive and precise. It seems to be more reliable than that recently described by Igarashi and McCann[4] since the results are not influenced by luteinizing hormone (LH). Moreover, the possibility of confounding due to diurnal release of gonadotrophins or other substances that might influence the uterine weight response in intact animals is eliminated.

The importance of unknown diurnal factors in mice is shown by the results of a series of FSH determinations after hypophysectomy performed either in the morning or the afternoon (Table 1). The *ED* of a number of gonadotrophic preparations, given alone to intact mice and to mice 5 h after hypophysectomy performed in the morning (8.30–10.30 a.m.) or in the afternoon (3–5 p.m.), and the 95 per cent limits of error are shown on the left-hand side of Table 1. On the right-hand side are the *ED*'s of FSH in the above preparations; these were estimated on the basis of augmentation of HCG when both were given 5 h after hypophysectomy. For a particular preparation either all assays were carried out simultaneously, or the *ED*'s are a mean of a number of determinations carried out on different occasions. In general, there have been no significant changes with time in sensitivity in this colony.

The results show wide differences between the preparations. The differences between assays are summarized in Table 2. It is generally believed that the mouse uterus test measures total gonadotrophin and the HCG-augmentation test measures FSH only.

Column 4 in Table 2 indicates the relative activities of the preparations for total gonadotrophin and FSH. On this basis the preparations fall into three categories: (*a*) Large differences—N.I.H.–FSH and Armour FSH are rich in FSH, but relatively inactive when given alone to hypophysectomized mice. (*b*) Small differences—N.I.H.–HPG and Armour LH are rich in FSH and also relatively active when given alone. (*c*) No change—N.I.H.–LH, ox pituitary fraction and pregnant mares' serum (PMS) evidently contain only small amounts of FSH. The first two are also relatively inactive gonadotrophins, whereas PMS is active in hypophysectomized animals.

Column 5 in Table 2 shows considerable differences in FSH potency between the preparations after afternoon as compared with morning hypophysectomy. The preparations again fall into three groups: (*a*) Large increase in potency was shown by the crude ox pituitary fraction. (*b*) Small increases in potency were shown by N.I.H.–FSH, N.I.H.–HPG and Armour FSH. (*c*) No change or a slight decrease in potency was shown by the remainder.

Table 1. Summary of the Results of Assays of Various Gonadotrophic Preparations giving the *ED*'s and their 95 per cent Limits of Error

Ox pituitary fraction	*NS*	*NS*	*NS*	800 · 1

NS, Not significant.

The results suggest certain lines of research:

(1) There was no diurnal effect on potency of PMS, given either alone or with HCG. This suggests that there is no diurnal variation in ovarian sensitivity *per se*; thus, there may be diurnal variation in circulating augmentative or inhibitory substances. Until this is settled, it will be impossible to carry out useful studies of specificity for gonadotrophins in intact animals.

(2) The hypotheses that the diurnal fluctuation in response is associated with diurnal release of gonadotrophin and that the time of release is influenced by the photoperiod have been examined (these results will be published separately elsewhere).

(3) It is evident that neither the PMS nor the LH used here contain any FSH that was able to augment HCG. The test as described could be useful to investigators who are attempting to separate the FSH portion of the molecule from the remainder.

(4) Replacing HCG with LH in the augmentation assay would be an important step towards an understanding of the relation between FSH and LH. Our investigations[2] indicate there is no augmentation between sheep FSH and sheep LH in uterine growth of hypophysectomized mice. However, it is possible that misleading results may be obtained by examining the biological action of gonadotrophins from one species in another species. Techniques for hypophysectomy in the calf and lamb are being investigated in this laboratory in order to carry out combined-action studies in homologous species.

(5) We are widening the scope of these investigations by determining the *ED*'s for ovulation in intact and hypophysectomized mice.

Materials used in these investigations were obtained from the following sources, to whom we are indebted: National Institutes of Health, Bethesda; Armour Laboratories, Chicago; Fawns and McAllan, Melbourne; and Dr. K. A. Ferguson, C.S.I.R.O., Sydney.

Diurnal Variation in the Spontaneous Ejaculations of the Male Albino Rat

IT is generally accepted that the sexual activity of the male rat is subjected to a diurnal variation. Thus, Beach and Levinson[1] and Larsson[2] have found that male rats in the presence of females are sexually more active under night conditions. In 1961 Orbach[3] demonstrated that the isolated male rat spontaneously ejaculates. The ejaculates yielded appear as plugs of coagulated semen which can be collected provided the animals are prevented from grooming the penis orally. In the course of an investigation I obtained figures which would be suitable for a study of the diurnal variation in such spontaneous ejaculations of the male albino rat.

Eight sexually inexperienced male albino rats (Sprague–Dawley), 6·5 months old at the beginning of the experiments, were prevented from grooming their penes by a 2 cm broad girdle, made from plaster of Paris, around the chest. Ventrally this girdle was firmly attached to a ring of galvanized iron-wire (diameter 1·5 mm) around the neck. The experiments lasted from April 21 until June 8.

The animals were separately caged in a windowless room and subjected to an artificial diurnal rhythm with a dark period extending from 8 p.m. to 8 a.m. A piece of paper was placed below the net-floor of each cage on which the seminal plugs were collected. Each cage was connected with a clock device and equipped with an electromagnet which automatically placed a sheet of paper below the floor every sixth hour, as indicated in Table 1. Consequently, the ejaculates were collected twice during the light and dark periods, respectively. The papers were removed once a day, and the number of plugs on each sheet of paper counted. The plugs were then dried over silica gel to constant weight.

Table 1. NUMBER OF PLUGS DELIVERED AT SPONTANEOUS EJACULATIONS DURING DIFFERENT PERIODS OF THE DAY

Conditions	Period	Rat No.:	No. of plugs I	II	III	IV	V	VI	VII	VIII	Sum
Light	8 p.m.–2 a.m.		29	16	17	16	18	19	17	35	167
Light	2 a.m.–8 a.m.		13	2	18	8	12	14	14	22	103
Dark	8 a.m.–2 p.m.		2	1	1	0	9	4	9	3	29
Dark	2 p.m.–8 p.m.		14	5	8	6	8	9	5	13	68

Table 2. MEAN WEIGHTS OF THE DRIED PLUGS

Period	Mean weight (mg)	*S.D.*
8 p.m.–2 a.m.	13·45	5·96
2 a.m.–8 a.m.	14·47	6·36
8 a.m.–2 p.m.	12·42	6·67
2 p.m.–8 p.m.	12·23	8·82

As seen from Table 1, there is a diurnal rhythm in the spontaneous ejaculations with the highest frequency between 8 p.m. and 2 a.m., the lowest between 8 a.m. and 2 p.m. The distribution of the plugs between different periods is not a random one ($\chi^2 = 112, f = 3, P < 0{\cdot}0005$). The mean weights of the plugs, on the other hand, do not differ significantly between the different periods (Table 2). Consequently, not only the number of ejaculates but also the amount of semen yielded are at a maximum during the first light hours of the day.

As male rats are sexually more active during the dark phase of their light–dark cycle[1,2], the frequency of spontaneous ejaculations found may be explained in the following way. The activity of the male organs is at a maximum during night conditions. In the presence of females the products of the sexual glands are delivered on copulation. When no copulations occur, as in isolated

males, the sexual products accumulate and may be delivered spontaneously, mainly at the end of the active period. It is, however, so far still an open question whether or not the presence of sexually active female rats modifies the sexual behaviour of the males.

Accumulation of Excessive Doses of Iodide by the Thyroid Gland of Normal, Hypophysectomized and Thyroxine-treated Rats

The accumulation of iodide by the thyroid gland is customarily measured subsequent to the administration of radioiodide and is expressed either as 'thyroid iodide uptake' (as a percentage of the administered dose) or as 'thyroid : serum radioiodide concentration ratio' (T/S ratio). The literature related to this subject-matter has been amply reviewed by Halmi[1] and more recently by Wolff[2]. Both these authors make it clear that besides thyrotrophin (TSH), other factors, such as dietary iodine for example, play an important part in the regulation of thyroidal iodine metabolism. This communication reports work dealing with the accumulation of inorganic iodide by the thyroid gland of animals subjected to various types of treatment and injected with doses of iodide large enough to practically block the organification of the accumulated iodide[3].

The experimental animals and the experimental procedures have already been described elsewhere[3,4]. Preliminary investigations showed that after the injection of large doses of iodide to normal rats, at any given dose-level, thyroid iodide increased progressively with time, reaching a maximum at 24 h. On the other hand, at any time interval, thyroid uptake values increased as the iodide dose was augmented; however, increasing the dose beyond 100 μg per rat—a dose large enough to block organification of iodide transported into the gland[2,5]—was followed by relatively small increments in thyroid uptake. In the experiments described here, an iodide uptake period of 6 h was arbitrarily chosen.

Rats were divided into different groups as follows: Group I, normal untreated rats; Group II, hypophysectomized rats in which iodide was injected (*A*) 3 days, and (*B*) 10 days after hypophysectomy; Group III, hypophysectomized rats in which iodide uptake was investigated 12 days after the operation and which were injected with TSH (Primothyron, Schering *A.G.*, Berlin) in doses of 0·5 U.S.P. U per rat per day for (*A*) 5 consecutive days, starting on the seventh day after surgery, and (*B*) 12 days, starting on the day following surgery; Group IV, normal rats treated for 14 consecutive days with *l*-thyroxine (25 μg per rat per day). All animals were killed for determination of thyroid iodide uptake 6 h after the injection of 0·1, 1·0 or 10·0 mg of iodide. One μc. of iodine-131 was injected along with the two smaller iodide doses used and 10 μc. with the largest dose used. The results of these experiments are shown in Table 1.

Whereas the thyroid iodide uptake by the normal rats was quite similar at the three dose-levels used, in all other groups increasing the dose resulted in notable increases in the amounts of iodide accumulated. In the hypophysectomized rats of Groups II (*A*) and (*B*), the removal of the hypophysis was reflected in a markedly reduced thyroid iodide accumulation with a dose of 0·1 mg I^-/rat; but, paradoxically enough, with the largest iodide dose used (10·0 mg I^-/rat), thyroid iodide uptake reached levels superior to those encountered in the comparable normal group. To check whether or not the lack of circulating TSH was responsible for this phenomenon, hypophysectomized rats were treated with TSH for 5 or 12 days prior to the uptake. A thyroid stimulation effect was apparent from a comparison of thyroid iodide uptake values of Group II (*B*) and Groups III (*A*) and (*B*); however, here again, although the thyroid iodide uptakes after a dose of 0·1 mg I^-/rat were but a fraction of the normal, with the highest iodide dose the thyroid iodide uptake exceeded that of the normal. Iodide uptake in the thyroxine-treated group following a dose of 0·1 mg I^-/rat was about four times higher than in the hypophysectomized rats of Group II (*B*), thus suggesting that thyroxine treatment does not suppress TSH secretion completely (as was pointed out elsewhere[4]). As the dose was increased to 10·0 mg I^-/rat, however, uptake in the hypophysectomized group was higher than in the thyroxine-treated group. With the lowest iodide dose used, the thyroids of the thyroxine-treated rats accumulated as much iodide as did the glands of rats 3 days after hypophysectomy or of TSH-treated hypophysectomized rats. Nevertheless, as the iodide dose was augmented, the uptake by the thyroid glands of the thyroxine-treated rats was much lower than in either of the latter two groups.

It might be surmized from the foregoing that, unless the noted results were due to the hyperthyroid state of the thyroxine-treated rats, some factor of adenohypophysial origin and other than TSH may play an important part in the control of thyroidal iodine metabolism. On the basis of present-day knowledge of thyroid physiology we can offer no other explanation for the above phenomena. Various additional possibilities were, however, also considered. 'Thyroid iodine uptake' is in reality a balance between iodine transported into the gland and iodine released from it. It may be assumed that in the normal rat an increase in iodide dose beyond a certain level results in no further changes in thyroid uptake because at this high iodide dose-level the rate of entry equals the rate of exit, or that the amount of iodide

§ Iodide was injected 12 days after hypophysectomy.

transported into the gland reaches a maximum while the exit of iodide remains constant. It is generally known that in the hypophysectomized rat the rate of accumulation of iodide is diminished due to lack of TSH stimulation, as is shown by considerably lower C_{mt} values (C_{mt} being the 'unidirectional clearance of radioiodide by 1 mg of thyroid tissue per minute'[1]). For these thyroids to accumulate more iodide than normal glands would require a marked inhibition of its release from the gland. It was actually shown that the K_{TB} (exit rate constant for thyroidal radioiodide[1]) of hypophysectomized animals is somewhat lower than normal[1,2]. However, if this were due to lack of TSH, then in the TSH-treated hypophysectomized rats the changes in iodide accumulation with increased iodide dose should have approached or at least paralleled those of normal. Diffusion into the gland was also considered, and the uptake values of all glands were corrected by the method proposed by Halmi[6], that is, by subtracting 40 per cent of the value for serum iodide (in mg/100 ml.) from that for thyroidal iodide (in mg/100 mg thyroid tissue). The application of these corrections did not affect the general trend of the results and, moreover, T/S ratios larger than unity were always observed. The increase in uptake with an increase in dose was more restrained in the thyroxine-treated group than in any of the other groups, except for the normal group. Thus it might be tentatively concluded that (1) in the presence of the anterior pituitary gland both entry of iodide into and its release from the thyroid gland are carefully controlled—and apparently not only by TSH—and (2) that when the anterior pituitary is ablated, this control is lost and the amount of iodide entering the gland increases in direct proportion to the increase in the dose of iodide given.

Epileptiform Seizures induced by Hypothalamic Stimulation in the Rat: Resistance to Fits following Fits

ELECTRICAL self-stimulation procedures in which animals operate pedal-switches to stimulate their own brains are sometimes disrupted by epileptiform seizures. These may appear as convulsive major attacks, or as brief pauses during which the subjects 'freeze' for about half a minute before they resume pedal pressing[1]. In a series of experiments that involved self-stimulation of the hypothalamus in more than thirty rats, we observed that the seizures occurred almost entirely at the beginning of the experimental sessions, and pedal pressing became more regular and rapid after the first few minutes. Fig. 1 is a typical record of this effect.

There are a number of possible causes for this progressive reduction in seizure activity during self-stimulation. A procedural consideration is that stimulus intensities were administered in descending order of magnitude in successive bouts. Also, since fits may be punishing[2], self-stimulating subjects may learn to hold the pedal down for briefer stimulus trains, or to respond at transiently slower rates, so as to avoid producing further fits from overstimulation. It is also possible that the occurrence of a seizure leads to a temporary change within the brain that affords protection against further fits. The following experiment tested these possibilities by administering intracranial stimulation in schedules that were not under the rat's control. In other respects the procedure followed was similar to that described elsewhere[3].

Six rats which had had overt convulsive attacks during previous self-stimulation trials were given a stimulus series of one-per-second, 0·5-sec, fifty-cycle trains from an automatic stimulator in four sessions on each of 2 days. Sessions were scheduled to follow each other at intervals of 30 min, 1 h, and 2 h, in counter-balanced order, and a session will be referred to by the intersession interval which preceded it. The sessions themselves were identical, and consisted of three bouts of 200 stimuli, each bout being followed by a 2-min rest period. The stimulus intensity for each subject was 10 or 20 μamp above the lowest intensity which induced major seizures in preliminary trials. These convulsive thresholds lay between 50 and 90 μamp, and were 10–30 μamp higher than the thresholds for self-stimulation.

Stimulation occurred in a glass tank, and during each bout subjects were closely watched for the onset of convulsions, at which point the stimulating current was switched off. The number of stimuli administered and the duration of clonic activity were recorded, and the bout was resumed 3 min after the seizure had ended.

Table 1. DISTRIBUTION OF FITS OVER BOUTS AND SESSIONS, THEIR MEAN DURATION, AND THE MEDIAN NO. OF STIMULI NEEDED TO PRODUCE THEM

Ranges are standard errors of the mean

	3	0		
After 0·5 h	1	0		
	2	0	—	—
	3	0		

* Includes two fits which occurred in the same bout. One bout yielded no fits.

Table 1 shows that only two of the thirty recorded fits occurred outside the first bout of a session, and that on only one occasion was there more than one fit in the same bout. Since stimuli were of constant intensity, rate, and duration, the progressive disappearance of fits during self-stimulation can therefore be ascribed to the onset of a central resistant state, and need not depend on changes in the stimulating current. The approximate duration of this resistant state can be inferred from the distribution of fits over sessions: the complete freedom from fits in the half-hour sessions had almost disappeared in the 2-h sessions (only two fit-free first bouts in twelve), and the six fits occurring in the 1-h sessions suggest that, with the current strengths used, about half the protective effect

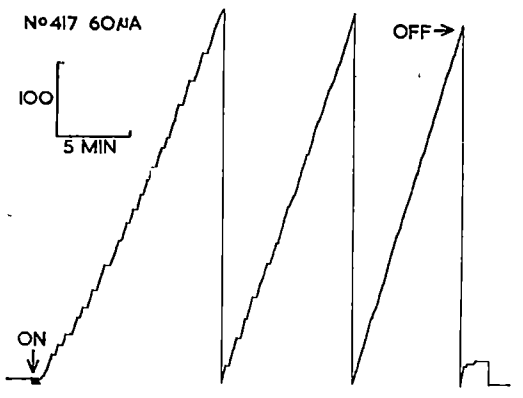

Fig. 1. Cumulative record of 1,500 lever presses during self-stimulation. The first part of the recording was interrupted by a series of non-convulsive seizures, giving the trace a saw-tooth appearance, but the later part of the record is smooth

was still present after 1 h. Table 1 also reveals that the 1-h fits were significantly less severe, in terms of duration, than those occurring in the initial sessions ($t = 2{\cdot}2$, $P < 0{\cdot}05$), and their production required significantly more shocks than the 2-h fits (Mann–Whitney $U = 11$, $P < 0{\cdot}05$).

Clinical evidence of post-ictal resistance to fits is necessarily difficult to obtain, but a recent report describes an epileptic patient in whom self-induced seizures conferred a temporary freedom from spontaneous attacks[4]. The neurological state underlying a resistance of this kind could explain why a fit stops[5], and why identical foci in different patients may or may not give rise to overt epilepsy[6].

PHARMACOLOGY

Effect of Promethazine Hydrochloride on Hand–Eye Co-ordination

The potential danger to driving and other tasks of barbiturate and antihistamine drugs has been emphasized[1]. While the former have been widely investigated, the central effects of antihistamine drugs are not fully realized, although they are easily accessible to the general public.

An investigation has been carried out into the effect of promethazine hydrochloride ('Phenergan') on visuo-motor co-ordination.

The apparatus consisted of a rotating drum (1 rotation/53 sec) covered with an insulating layer in which 400 holes had been cut. On the 'disk-dotting' principle, and using a steering wheel of 18 cm diameter, the subject followed the irregular course of the holes, so establishing electrical contact and recording the score on a digital computer.

Four healthy male students, aged between 21 and 23 years, took part in a double-blind cross-over experiment in which promethazine hydrochloride (50 mg) was compared with a placebo at 2-weekly intervals. Each subject was fully familiarized with the technique in order to minimize learning effects. They abstained from stimulants and cigarettes during the experiment.

Before, and at 1, 2 and 3 h after administration of the drug or placebo, measurements were recorded over eight rotations of the drum, with an interval of 1 min between each rotation.

The mean values of the highest score of each determination at any one time in the four subjects were obtained and the results are shown in Fig. 1. Promethazine hydrochloride produced a significant fall in score ($P < 0{\cdot}05$) compared with the placebo at 3 h, but no significant difference was seen at 1 and 2 h.

The mean of each eight determinations was compared with the highest value of the same for each occasion in each subject. A highly significant correlation was found between them ($r = 0{\cdot}882$, $P < 0{\cdot}001$).

Although antihistamine drugs are known to produce varying degrees of central nervous depression, few controlled trials have been carried out on specific functions. Impairment of visual flicker discrimination by diphenhydramine (25 mg) was demonstrated by Roback, Krasno and Ivy[2], and Payne[3] found that meclozine (50 mg) significantly impaired memory for verbal material. On the other hand, Colquhoun[4] was unable to detect significant impairment of vigilance or short-term memory after administration of meclozine (50 mg) although it was marked if the drug was given together with 32 g ethyl alcohol.

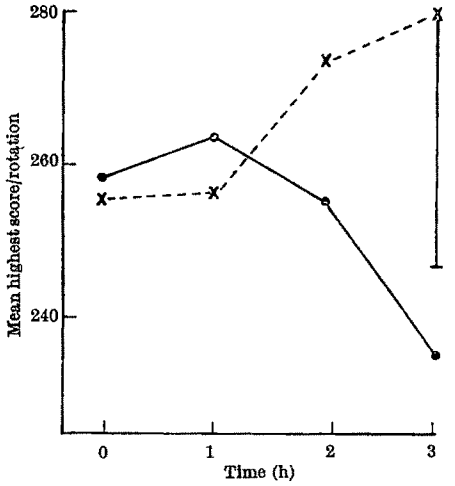

Fig. 1. Changes in mean highest score/rotation at 0, 1, 2 and 3 h after administration of promethazine hydrochloride (50 mg) (——) and placebo (- - - -) in four subjects. The 95 per cent confidence limits (1-tail test) were shown for placebo at 3 h

The present results demonstrate that promethazine hydrochloride significantly impairs hand–eye co-ordination. The dose used was sufficient to produce subjective symptoms of central depression in all the subjects, and further experiments are planned to investigate more fully the effect of smaller doses of this and other antihistamine drugs. This is of importance in view of the ease with which these drugs can be obtained by the general public, and of the possible hazards involved in driving and other complex tasks.

The apparatus used in this experiment was easy to construct and the subjects readily became proficient in its use.

We thank Prof. W. P. Colquhoun, Prof. M. Weatherall, Prof. E. F. Scowen, Dr. A. H. Goodspeed and the staff of Northampton College for their advice. Messrs. E. Langcaster and E. Caswell assisted in the design and construction of the apparatus, and students of Northampton College co-operated as subjects for the experiments. May and Baker, Ltd., provided tablets of promethazine and placebo. One of us (P. T.) is in receipt of a Wellcome senior research fellowship in clinical science.

Effect of Malachite Green, Congo Red and Safranin on Cell Division in Gemmae of *Allium cepa*

Some evidence has been published that certain organic dyes induce inflammatory conditions and even give rise to carcinogenic processes. All these substances belong either to the aromatic order or to heterocyclic compounds containing aromatic rings. The reports published on the harmful effects of these dyes deal as a rule with cases of diseases caused by dyes used in factories and laboratories. The evidence given in these reports is not entirely conclusive, because in production processes the workers come into contact with initial or intermediate products which exert a toxic influence. This is particularly so because many of the intermediate products are amino- or nitro-derivatives of the aromatic order. It is, therefore, evident that in order to solve this problem, experimental investigations on dyes suspected of a toxic or carcinogenic effect are necessary.

Since we are interested in the problem of the effect of carcinogenic compounds on the cell nucleus and its division, it was from this aspect that we commenced our experiments. The gemmae of the underground portion of the onion shoot (*Allium cepa* L.) were used for these experiments.

In carrying out experiments with this material, it was possible to take into consideration only water-soluble dyes. For this reason, from the dyes suspected of carcinogenic properties, we considered Congo red, malachite green and safranin to be the most suitable for our experiments.

We prepared aqueous solutions of these dyes in concentrations of 10^{-3}, 10^{-4}, 10^{-5} and 10^{-6} per cent. The morphological effector in our experiments was the gemmae of the onion root (*Allium cepa* L.). All the plants were divided into three groups according to the type of dye to be investigated.

Each of these groups was then divided into five groups according to the concentration of the dye, one group being the control group. The plants of the control group grew in distilled water. Since the period of growth for the root lasted only 5 days we did not use any medium, the food reserves in the cotyledons being quite sufficient for that length of time. The onions were placed on cellulose tissue in Petri dishes and covered with 150 ml. aqueous solutions of the dyes. Five days later, ten roots from each of the groups were cut off. The roots were cut 5 mm from tip and prepared by the paraffin method, after which microtome sections 6μ thick were cut. The sections thus prepared were used for the counting of cell divisions. In our calculations, the various phases of division were taken into consideration as well as all deviations from normal mitotic division. The values obtained from each concentration were compared with the values noted in the control group by means of the χ^2 test. As a zero hypothesis, it was assumed that there were no significant differences between the values investigated and therefore these values should not differ from the mean arithmetical values of the group compared. Significant differences were marked '+' (the level of significance being taken to be $\alpha = 0{\cdot}01$). In order to avoid a more detailed description of the findings, we have presented them in table form. Table 1 shows the various phases of division and indicates the normal and pathological divisions. The figures given in the table are the mean values of 10 readings. They were calculated as the mitotic index for approximately 200 cells. In the last column the statistical significance of the observed differences is given. The total number of normal and pathological divisions are presented in Fig. 1. In order to ensure an even distance between the concentrations on the axis, an axis = 7 + log of the concentration was used.

Congo red may lead to neoplasms, for example, cancer of the bladder.

Malachite green is strongly toxic to the rabbit, and safranin causes inflammation of the skin and may lead to the growth of malignant neoplasms of the bladder[1].

Investigations on the mitotic activity of various chemical compounds are usually carried out on three models. The model most frequently used is the gemma of the underground shoots of plants from the Liliaceae and Papilionaceae families[2,3]. A modification of this method is used when the investigations are carried out on excised roots[4]. Rapidly dividing animal tissue and tissue culture are also used[1,5–7]. Investigations on the effect of carcinogenic substances, anti-mitotic factors and X-rays have been carried out on these models[3,8]. Keyl and Werth[9], in their cytological investigations on salivary gland chromosomes, found that malachite green caused changes in the structure of those chromosomes.

In our department we have investigated the effect of various salts of the ferrous group (cobalt, nickel and iron) on mitotic processes[2]. In all these investigations, we observed changes in the nucleus, cytoplasm and in cell division. One of the most significant symptoms was a marked disturbance in the mitotic processes of the cells. For this reason, in our investigations, we took into consideration only the effect of aqueous solutions of the dyes on mitotic processes. In each of our experiments it was found that aqueous solutions of the dyes had a stimulatory effect on the mitotic processes and gave rise to a considerable number of abnormal cell divisions.

On the basis of these experiments, it was possible to draw the following conclusions: (1) Some of the dyes used in histological techniques and belonging to the aromatic order or to heterocyclic compounds containing an aromatic ring have an effect on cell division. (2) This effect is manifested in stimulation of cell division, that is, in a higher mitotic index. (3) After exposure of the plants to the action of aqueous solutions of the dyes, a greater number of abnormal divisions is observed. (4) The character of these changes corresponds to those observed when investigating other carcinogenic compounds.

Hydrolysis of Di(aziridin-1-yl)sulphoxide to Ethyleneimine

Di(aziridin-1-yl)sulphoxide (DESO), which was synthesized as a potential anti-tumour agent, has been shown to possess the property of liberating ethyleneimine in the presence of phosphate ion[1]. This communication reports a more detailed investigation of this effect. Ethyleneimine assay involved the colorimetric measurement (at 420 mμ) of the chloroform extractable dye obtained by reaction of the base with 1,2-naphthaquinone-4-sodium sulphonate in barbitone buffer (0·1 M, *p*H 9·6) The production of ethyleneimine from DESO was verified by comparing the absorption curves of the dyes derived from ethyleneimine and DESO (absorption maxima 303 and 425 mμ). On incubating DESO (2 mg/ml., 37° C) for 2 h in barbitone buffer over the *p*H range 6·4–8·0 there was never more than 3 per cent hydrolysis, but at *p*H 6·5 in phosphate buffer there was 74 per cent conversion to ethyleneimine. DESO was also quite stable on incubation in water, but addition of phosphate buffer resulted in the rapid production of ethyleneimine[1].

(DESO)

In 2·5 M phosphate buffer, *p*H 6·5, DESO (2 mg/ml.) yielded 100 per cent of its ethyleneimine in 10 min. Using 1 M and 0·5 M buffer, 83 and 67 per cent respectively of the available ethyleneimine was liberated in the same period, indicating hydrolysis to be dependent on phosphate ion concentration. On incubating the sulphoxide (0·5 mg/ml., 0·0038 M), in barbitone buffer containing graded amounts of phosphate, the amount of DESO converted during 2 h was proportional to the logarithm of the phosphate concentration when the latter was 0·3–6 mg/ml. (0·0032–0·063 M) (Fig. 1). At ion concentrations of 6–30 mg/ml. (0·32 M) the yield of ethyleneimine was not increased to more than 85 per cent and the *p*H of the solution was reduced.

The rate of ethyleneimine formation, in phosphate buffer, increased with diminishing *p*H and a linear rate of reaction was obtained up to the time when 40–50 per cent of ethyleneimine radicles had been removed from the parent compound (Table 1). It thus appears that one ethyleneimine ring is more readily liberated, although breakdown as a whole depends on phosphate ion concentration.

The mechanism of the phosphate effect has not been established, but a definite reaction between DESO and phosphate is implied, otherwise catalytic amounts of the latter would permit ethyleneimine liberation and the relation shown in Fig. 1 could not exist. It may be that reaction occurs in some way with the H_2PO_4' form, the amount of which also increases as *p*H is reduced.

As regards other ions, sulphate and chloride (up to 0·5 M) had no effect, but sulphite and thiosulphate (0·067 M) caused DESO (2 mg/ml.) to yield 18 and 24 per cent

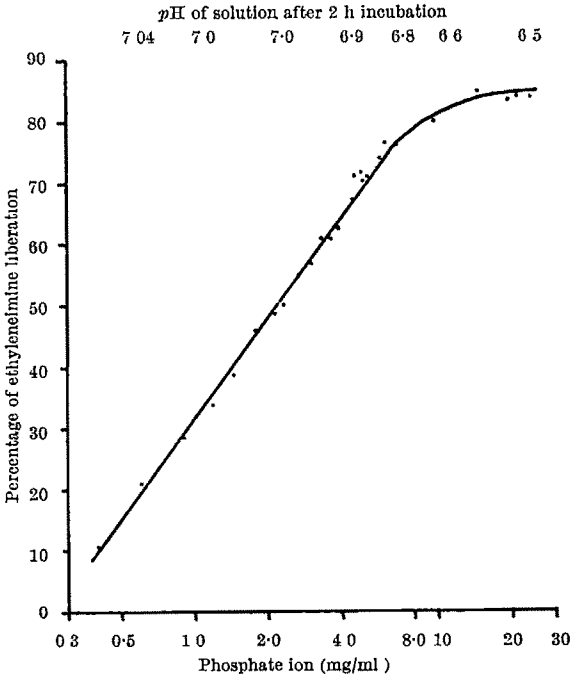

Fig 1 Ethyleneimine production by di(aziridin-1-yl)sulphoxide (0 5 mg/ml.) when incubated (2 h) with various amounts of phosphate in 0·1 M barbitone buffer (0 1 M *p*H 7)

Table 1. Rate of Ethyleneimine Production by Di(aziridin-1-yl)-sulphoxide (1 mg/ml.) when Incubated (37° C) in Phosphate Buffer (0·067 M: *p*H 5·3–8·0)

Time incubated (min)	Percentage of available ethyleneimine liberated			
	*p*H 5·3	*p*H 6·3	*p*H 7	*p*H 8
10	24	20	12	3
20	42	36	23	6
30	54	49	32	9
40	62	57	41	11
50	67	62	47	14
60	69	65	54	16

respectively of ethyleneimine by 2 h. *NNN'N'*-diethyleneurea, which is structurally related to DESO (carbon replacing sulphur), only yielded ethyleneimine in alkaline solution and then only in small amounts (6 per cent in 3 h, *p*H 8).

While it is generally agreed that the chemical reactivity of ethyleneimine derivatives forms the basis of their tumour-inhibitory activity, little is known about the *in vivo* circumstances which may contribute to or inhibit the biological effect. It is possible that the present data explain why DESO fails to inhibit the growth of experimental tumours, since ethyleneimine lacks tumour-inhibitory activity[2].

I thank Dr. H. Jackson for his advice in the preparation of this article.

Serum Concentration of Phenylbutazone in Tests for Antiphlogistic Activity and under Clinical Treatment

Owing to marked individual variations in the rate of metabolic transformation in man, the daily doses of phenylbutazone used in therapy show a relatively wide range. Burns *et al.*[1] found a biological half-life for phenylbutazone ranging from 1·5 to 6 days, and correspondingly found plateau plasma concentrations ranging from 60 to 150 mg/l. in different individuals. After an initial dose of 800 mg orally followed by 200 mg four times daily, Wilson *et al.*[2] found plasma concentrations from 50 to 100 mg/l. and consider these concentrations necessary for therapeutic effect. Currie[3] found 80–110 mg/l. at the beginning of the therapy and later under maintenance dose-levels of 46–80 mg/l. Bruck *et al.*[4] are of the opinion that, in order to avoid side-effects, plasma concentrations should not exceed 100 mg/l., and during treatment they maintained concentrations of between 50 and 90 mg/l. They propose that treatment should begin with 200 mg per day orally, and that the dose should increase by 100 mg daily until the response is satisfactory.

On an mg/kg base these doses lie considerably below those necessary for the demonstration of antiphlogistic effects in animal experimentation. In experiments in this laboratory, these doses amounted to 25–50 mg/kg when a maximal reduction of several forms of experimental oedema in rats was to be achieved[5,6].

Since it seemed possible that the difference in the dose might be compensated for by the much shorter half-life of phenylbutazone in the rat, we decided to compare the serum concentrations reached after oral application of doses effective in the different tests for antiphlogistic activity in the rat with those determined in patients under treatment with phenylbutazone.

Phenylbutazone was determined spectrophotometrically using the method of Burns *et al.*[1]. Fig. 1 shows the serum concentrations after oral application of 10, 25, and 50 mg/kg in male and female rats. The concentrations present during 5½ h (the duration of the test for antiphlogistic activity) agree closely with those obtained under clinical treatment for the two higher doses. The lower serum concentrations after a dose of 10 mg/kg correspond to the submaximal effect in the test for antiphlogistic activity[5,6]. We are inclined, therefore, to regard the effect of phenylbutazone on the different models of inflammation used in our laboratory (kaolin, aerosil and carrageenin) as a true correlate of clinical antiphlogistic activity, the more so as a similar sensitivity of peripheral processes to drugs should exist even in different species.

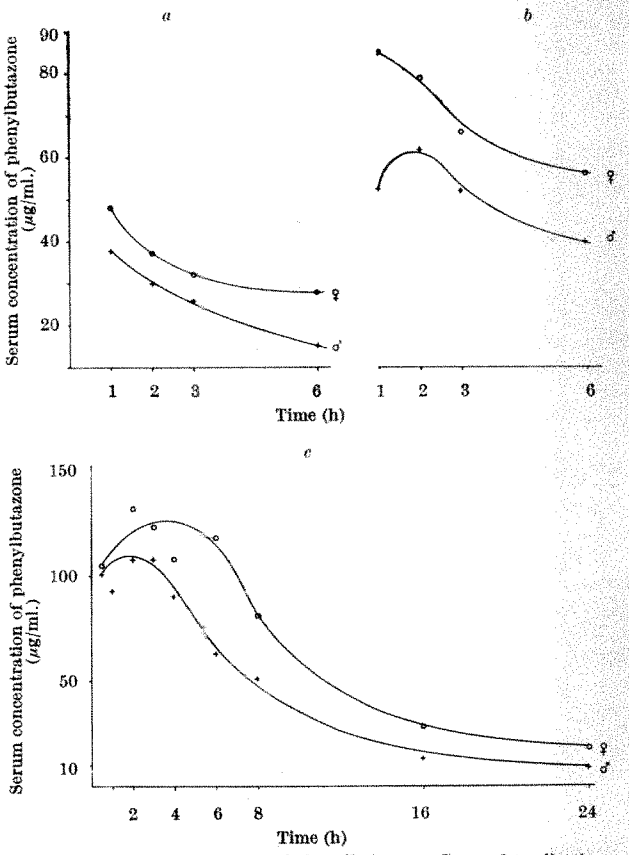

Fig. 1. Serum concentrations of phenylbutazone after oral application to male and female rats (Leo strain). Dosage: *a*, 10 mg phenylbutazone/kg; *b*, 25 mg phenylbutazone/kg; *c*, 50 mg phenylbutazone/kg

It can be seen from Fig. 1 that the concentrations obtained in female rats were always higher than those in the male ones. This sex difference cannot be explained by a different metabolic rate alone, since the half-lives determined for both sexes lie rather close together (5·2 h for the males, 6 h for the females), and since the difference could not be abolished by pretreatment with *SKF* 525-*A*. Besides the difference in half-life, a lower volume of distribution and a higher haematocrit were found in our female rats, all three factors contributing to the higher phenylbutazone serum concentrations in this sex.

HAEMATOLOGY

Gm(b) Factor in the γ Globulin of Non-human Primates

Recent investigations in man have shown that the Gm factors of γG globulin are linked to non-segregating antigenic determinants which define at least four different classes of heavy polypeptide chains in human γG globulin[1]. Studies in man have also suggested that the Gm(b) factor is not unique, but rather is pleomorphic and may vary in different human races[2]. Certain of the Gm genetic factors including Gm(b) have been recognized in the serum of some non-human primates[3,4]. It therefore became of interest to assess the Gm(b) factor as it occurred in non-human primates, to evaluate any pleomorphism and to investigate its relationship to the H-chain sub-group with which the Gm(b) factor is known to be associated in man.

Table 1. Inhibition of Gm(b) Typing Systems by γ Globulin of Different Primates

* Isolated from pooled serum.
† Isolated from individual serum.

Seven representative species from five different primate families are represented in these investigations: *Hominidae* (man), *Pongidae* (gorilla, chimpanzee), *Cercopithecidae* (old world rhesus monkey, baboon), *Cebidae* (new world spider monkey) and *Callithricidae* (tamarin). Serum pools from each species represented the contribution of 3–12 different animals with the exception of gorilla serum from a single animal. Gamma globulins were isolated by zone electrophoresis in starch. Gm typing was performed by an inhibition of agglutination technique as previously described[5] utilizing three different anti-Gm(b) agglutinators: (*a*) that from a rheumatoid human, (*b*) that from a rhesus monkey which had been immunized with human Gm(b+)γG heavy chains and the serum of which was then absorbed with a human Gm(a+b−) serum, and (*c*) that from a non-rheumatoid human. Each system used red cells coated with an appropriate incomplete anti-D, and gave concordant results in the typing of 21 Gm(b+), 8 Gm(a+b−) and 1 Gm(b+f−) human sera from the White and Negro races. Table 1 presents results of typing the various primate γ globulins. As shown, the rheumatoid agglutinator was inhibited by human and gorilla γ globulins to an equivalent degree, somewhat less by chimpanzee γ globulin, and no inhibition was seen by the other γ globulins. Inhibition of the monkey anti-Gm(b) agglutinator was obtained only by human γ globulin, while investigations with the non-rheumatoid human agglutinator gave strikingly different results. Marked and quantitatively similar inhibition was obtained by γ globulins from man, gorilla, chimpanzee, old world (rhesus) monkey and baboon, while the new world (spider) monkey and tamarin failed to inhibit even at 1 mg/ml.

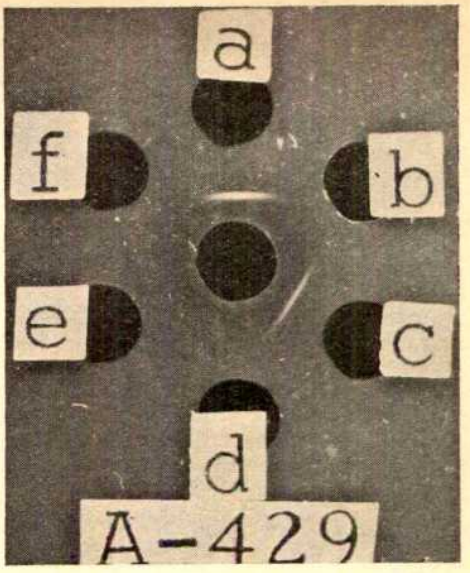

Fig. 1. Reaction of monkey anti-Vi antiserum (centre well) with (*a*) Gm(b+) myeloma protein at 1 mg/ml.; (*b*) gorilla γ globulin at 10 mg/ml.; (*c*) human γ globulin at 10 mg/ml.; (*d*) Gm(a+) myeloma protein at 1 mg/ml.; (*e*) monkey γ globulin at 10 mg/ml.; (*f*) chimpanzee γ globulin at 10 mg/ml.

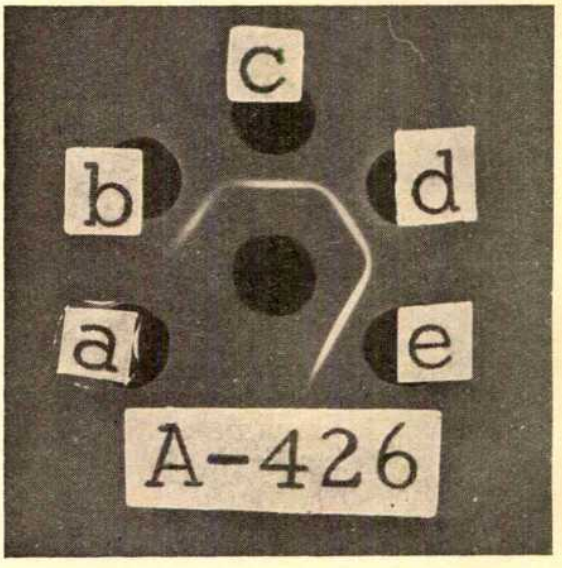

Fig. 2. Reaction of monkey anti-Vi antiserum absorbed with 8 mg per ml. antiserum of (*a*) human γ globulin; (*b*) chimpanzee γ globulin; (*c*) gorilla γ globulin; (*d*) monkey γ globulin; (*e*) tamarin γ globulin; a Gm(b+) myeloma protein at 1 mg/ml. (centre well)

A precipitating antiserum prepared in the monkey against Gm(b+) human γG H chains was specific for the Vi H-chain sub-group after appropriate absorption. This sub-group has previously been shown to be associated with the Gm(b) factor in human γG globulin[1]. Search for the Vi H-chain sub-group determinant with this antiserum was performed in a number of ways. First, double diffusion in agar against γ globulins at concentrations of from 1 to 20 mg/ml. failed to reveal precipitin lines, as shown in Fig. 1. Also, quantitative precipitin investigations with monkey and chimpanzee γ globulins failed to detect precipitated antigen. In order to search for the presence of cross-reacting but non-precipitating Vi antigen, inhibition studies were also done. Aliquots of anti-Vi antiserum were absorbed with quantities of the various γ globulins equal to more than twice the amount of human

γ globulin necessary to absorb completely anti-Vi activity. Typical results are shown in Fig. 2, in which Vi-specific activity remained after absorption. In addition, investigations utilizing inhibition of quantitative precipitation of human γ globulin at the equivalence point by the various primate γ globulins also failed to demonstrate Vi specific antigens in the non-human primates.

These studies would suggest that the Gm(b) factor is not only a mosaic of determinants varying between human races and in certain non-human primate families, but is also probably composed of more than a single determinant in the γG globulin of a single individual. Clearly, the Caucasian Gm(b) has one determinant which is not shared with non-human primates and which was detected in these investigations by an anti-Gm(b) raised in a rhesus monkey. One might anticipate that Gm(b) positive non-human primates may have a similar determinant in their Gm(b) 'area' which is specific for that particular primate family. In addition, at least one Gm(b) determinant found in Caucasian and Negro Gm(b) positive γ globulin occurs in the γ globulin of the *Pongidae* and *Cercopithecidae*, as is evident from their inhibition of the Gm(b) specific haemagglutination system utilizing an agglutinator from the non-rheumatoid human. This probably does not represent simple cross-reactivity in that the inhibition was quantitatively similar to that by human γ globulin. In addition, at present it is conceived that Gm specific agglutinators from non-rheumatoid donors are a uniquely specific form of anti-Gm agglutinator. It is impossible, however, to exclude cross-reactivity between similar but not identical Gm(b) determinants. There is no clear explanation of the variable degrees of inhibition seen in studies with the Gm(b) specific rheumatoid agglutinator. Such reagents may, in fact, be detecting several determinants of the Gm(b) mosaic, which may in turn appear in varying degrees in the non-human primates. Alternatively, cross-reactivity may have influenced results with this reagent to a significant degree.

The failure to demonstrate the Vi antigen to accompany Gm(b) determinants in the *Pongidae* and *Cercopithecidae* is of some interest. It is, of course, impossible to exclude totally the presence of this antigen. It is known that different anti-Vi-specific antisera may detect different areas of the γG globulin molecule[6]. If this indicates polymorphism of the Vi determinant, the use of the Vi specific monkey antiserum may have precluded demonstration of its presence. The most that can be said is that this determinant as it is recognized in man does not seem to occur in association with a Gm(b) determinant recognized by a human agglutinator in these primate γ globulins. This would support the original concept that the H-chain sub-group determinants are distinct from, but linked to, the Gm characters and occur in the same area of the H polypeptide chain, rather than the alternative suggestion that they are an epistatic configuration the structure of which is necessary for the appearance of the Gm(b) factor.

I thank Drs. E. Melby, H. Fudenberg and L. Martensson for certain primate sera and reagents used in this investigation, which was supported by grant *AI* 05780 from the National Institutes of Health, Bethesda, Maryland.

HISTOCHEMISTRY

Ribonuclease and Deoxyribonuclease Substrate Film Methods: a Pitfall in the Interpretation of Results

DURING the course of histochemical investigations into various metabolic disorders, the substrate-film methods for the demonstration of ribonuclease and deoxyribonuclease[1,2] were examined. Satisfactory thin films were obtained by dipping chemically cleaned slides into the DNA or RNA gelatine mixtures at 60° C and then shaking off the excess liquid. The films were allowed to stand vertically at 60° C for 5 min before wiping clean the bottom quarter of the slide. This procedure gave stable films which did not lift or distort during the subsequent operations of fixation in formalin, incubation and staining. The gelatine was obtained from B.D.H. ('Gold Label' grade), and the DNA and RNA from L. Light.

The apparent distribution of DNase and RNase in tissue sections shown by the methods cited[1,2] led to the conclusion that not all the activity could be attributed to the respective enzyme. It was thought that quite a considerable proportion of the apparent activity was due to proteolytic enzymes dissolving the gelatine film, even though formalin fixed, thus releasing the substrate non-specifically. To test this hypothesis, substrate films of RNA and DNA were prepared in the normal manner and 0·1 ml. water, 0·1 ml. ribonuclease 0·01 per cent, and 0·1 ml. trypsin 0·01 per cent were placed separately on each film and the slides were incubated at room temperature for 1 h. The slides were then washed and stained for 10 min with 2 per cent toluidine blue.

The water controls left both films completely untouched and ribonuclease digested only the RNA film. Trypsin completely digested both films. From these results it is concluded that the present substrate film techniques for ribonuclease and deoxyribonuclease can lead to false results unless the gelatine used is found to be resistant to tryptic digestion after formalin fixation. Much of the apparent activity using B.D.H. 'Gold Label' gelatine is due to the action of proteolytic enzymes. Further work is in progress incorporating inhibitors in the gelatine substrate films and using agar as an alternative supporting medium.

I thank D. Barry for technical assistance. This work is supported by a grant from the National Society for Mentally Handicapped Children.

IMMUNOLOGY

Mouse Thymic Iso-antigens

Old, Boyse and Stockert reported the presence of a common iso-antigen (*LT*) in certain leukaemias of two strains of mice, and in thymus of only one of these strains and one unrelated strain[1]. Later, the *LT* iso-antigen was found in normal thymus of eight out of twenty-four strains[2]. The *LT* iso-antigen was not detected in the normal tissues examined other than thymus[1,2].

Following our initial report of a strong antigen associated with thymic lymphocytes of *AKR* mice[3], thymocytes from eighteen strains of mice were found to possess either the θ-*AKR* or the θ-*C3HeB/Fe* iso-antigens on their surface[4]. These thymic antigens were distinct from *LT*. In the four to six strains of mice that were tested further, neither splenic lymphocytes nor lymph node lymphocytes were cytolysed by iso-antisera that cytolysed thymocytes.

Absorption experiments indicated that splenic and lymph node lymphocytes possessed a low percentage of the θ-iso-antigens present on thymocytes. Among the strains tested, no exceptions were found[4]. Results were sufficient to establish the immunological distinction of *AKR* thymocytes[5].

This communication extends the foregoing findings to eighteen strains or sub-strains of mice. Use of an *AKR* iso-antiserum almost fifty times more potent than previously used[4] has permitted increased precision. Since again no exceptions were found, immunological distinction of thymocytes seems confirmed as a general phenomenon in mice.

The potencies of iso-antisera for immune cytolysis of lymphocytes were determined in a small-scale assay system[4]. Absorptions of iso-antisera by lymphocytes were carried out by a quantitative adaptation[4] of the method of Möller[6] and Amos *et al.*[7]. These two methods should give complementary results, since Möller and Möller have shown that cytolytic potencies are directly related to the content of iso-antigens on the cell surface[8].

Iso-antisera to thymocytes were previously prepared by six weekly intraperitoneal injections of viable thymocytes, plus a single subcutaneous injection of thymocytes incorporated in complete Freund–McDermott adjuvant[4,5]. Immunization of groups of three *C57BL*/6 mice by various schedules showed that adjuvant actually depressed the immune response (Table 1, groups *C* and *G*), perhaps because of the relatively high dose injected (0·2 ml.). A single intraperitoneal injection of viable thymocytes produced detectable sensitization (group *A*).

Table 1. Effectiveness of Immunization of *C57BL*/6 Mice by *AKR* Thymocytes

Group of *C57BL*/6 mice	No. of weekly intraperitoneal injections of *AKR* lymphocytes	No. of subcutaneous injections of adjuvant	Interval between injections and bleeding (days)	Cytolytic potency* of serum against *AKR* thymocytes

* Cytolytic potency is expressed as 100/cytolytic titre.
† The highest cytolysis obtained was 19 per cent above the control-level.

Potent *AKR* iso-antiserum to *C3HeB/Fe* thymocytes was prepared by the most effective schedule of injections (Table 1, group *C*). This iso-antiserum cytolysed thymocytes from mice possessing the θ-*C3HeB/Fe* iso-antigen at high potencies; in contrast, splenic or lymph node lymphocytes were not cytolysed in excess of 28 per cent above the control value (Table 2). Equivalent data were previously reported for cytolysis of lymphocytes from mice that possess the θ-*AKR* iso-antigen (namely, *AKR* and *RF* mice) by *C3HeB/Fe* iso-antiserum[4]; lymphocytes from the *RFM/Un* sub-strain of *RF* mice have now been found to react in a similar manner to those of the parent strain.

The absorptive capacity of splenic lymphocytes was between 6 and 21 per cent of that of thymocytes (Table 3). Equivalent data have previously been reported for *AKR* mice[4]. Since it is known that a critical concentration of iso-antigens must be present on the cell surface before cytolysis can occur[8,9], the present results of cytolysis and absorption experiments are compatible.

* Calculated relative to absorption by the same number of *C3HeB/Fe* thymocytes.

Crosses were made between *AKR* and *C3HeB/Fe* mice. Thymocytes from the F_1 offspring were cytolysed both by iso-antisera to the θ-*AKR* iso-antigen and by iso-antisera to the θ-*C3HeB/Fe* iso-antigen. The cytolytic potencies were, on average, 39 per cent lower than against thymocytes from the parent strain, which could only be cytolysed by one or other of the two iso-antisera (Table 2, and ref. 4). Similar results were obtained with thymocytes from F_1 offspring of a mating between *RF* and *C57BL*/6 mice. Thymocytes from (*AKR* × *C3HeB/Fe*)F_1 mice absorbed respectively 70 and 66 per cent as much of the two iso-antisera as thymocytes from the respective parents. These data are consistent with a theoretical absorption at an intermediate value, possibly 50 per cent, which would be expected if the θ-*AKR* and θ-*C3HeB/Fe* iso-antigens represented alleles of a single locus that has two sites. Inbred mice are homozygous with respect to one or other of these alleles, and both antigens are expressed in the heterozygous state.

With regard to chemical nature, the θ-*C3HeB/Fe* iso-antigen of thymus was non-dialysable, and could not be recovered in active form after treatment[10] with lipid solvents, such as chloroform–methanol (2 : 1), at 0° C. Treatment with sodium deoxycholate at concentrations between 1 and 30 mg/ml., followed by exhaustive dialysis to remove the deoxycholate, did not increase the antigenic activity of the supernatant obtained after centrifugation at 35,000*g*. On the basis of unit nitrogen content, the microsomal fraction[11] of a homogenate of *C3HeB/Fe* thymus was nineteen times more potent than the whole homogenate, when tested for absorption of an *AKR* iso-antiserum prepared against *C3HeB/Fe* thymocytes. These data suggest that the θ-*C3HeB/Fe* iso-antigen is a lipoprotein.

In the mouse, presence of the *LT* iso-antigen in certain strains that possess the θ-*C3HeB/Fe* iso-antigen indicates that a single inbred strain may possess more than one thymic antigen[4]. In man, the presence of auto-antibodies directed against both thymus and muscle in one-third of a series of patients with myasthenia gravis[12] suggests the presence of iso-antigens shared between thymus and muscle, although other explanations are possible. Both in the mouse and in man much further work seems required to delineate the presence, distribution and significance of thymic antigens.

This investigation was supported by a grant from the Medical Foundation, Inc., and by the General Research Support Grant of Boston City Hospital. We thank Dr. George D. Snell, of the Jackson Laboratory, for advice on the genetic aspects of this investigation, and also Prof. Gerhard Schmidt, of Tufts Medical School, for advice on the procedures involving lipid chemistry.

Mouse Nervous Tissue Iso-antigens

MUCH work has been done on experimental auto-immunization with nervous tissues, and the relation of the resulting pathology to that found in demyelinative diseases of the human nervous system[1]. Furthermore, the existence of organ-specific lipid haptens has long been recognized; recently, Joffe, Rapport and Graf have identified one of these haptens as a galactocerebroside[2]. No strain-specific iso-antigens were described by these authors[1,2].

We recently described two strain-specific iso-antigens, θ-*AKR* and θ-*C3HeB/Fe*, one or the other of which is present at a high concentration in adult brain and thymus of all mouse strains that were tested[3,4]. In new-born mice of the four strains investigated, these antigens were found at a high concentration only in thymus; neonatal brain contained between 1 and 3 per cent of the antigen concentration found in adult brain. Thus, the two antigens appeared to originate either in thymus or in closely related cellular precursors. These θ-iso-antigens were present at much lower concentrations in lymph node lymphocytes, splenic lymphocytes, appendix, lung and liver. Some leukaemias from *AKR* mice possessed a high content of the θ-*AKR* iso-antigen, while others, apparently of non-thymic origin, possessed a low content. These data were obtained by use of immune cytolysis and of a quantitative absorption procedure[4].

In the present investigation, the same methods but more potent iso-antisera were used. Results of absorption experiments are expressed as the absorptive capacity per unit wet weight of brain. Since the iso-antisera used showed high specificity in their absorption by different tissues, absorptive capacity is taken to parallel the content of θ-iso-antigens[4].

The appearance of θ-iso-antigens in brain of three strains of mice (Fig. 1) paralleled the histological[5,6] and physiological[7] maturation of mouse brain. The θ-iso-antigens remained at very low levels for the first 4 days after birth. Between 10 and 20 days of age, the antigen content rose from approximately 15 to 62 per cent of the adult-level, which was reached at 5–6 weeks of age (Fig. 1).

In addition, groups of two *C3HeB/Fe* mice aged 14, 18, 33, 57 and 81 weeks were investigated for antigen changes. All mice were male except for the youngest group. The mean relative content of θ-*C3HeB/Fe* iso-antigen per unit wet weight of brain was 100, 99, 87, 93 and 101 per cent, respectively. Thus, no significant change in antigen content was observed during adulthood.

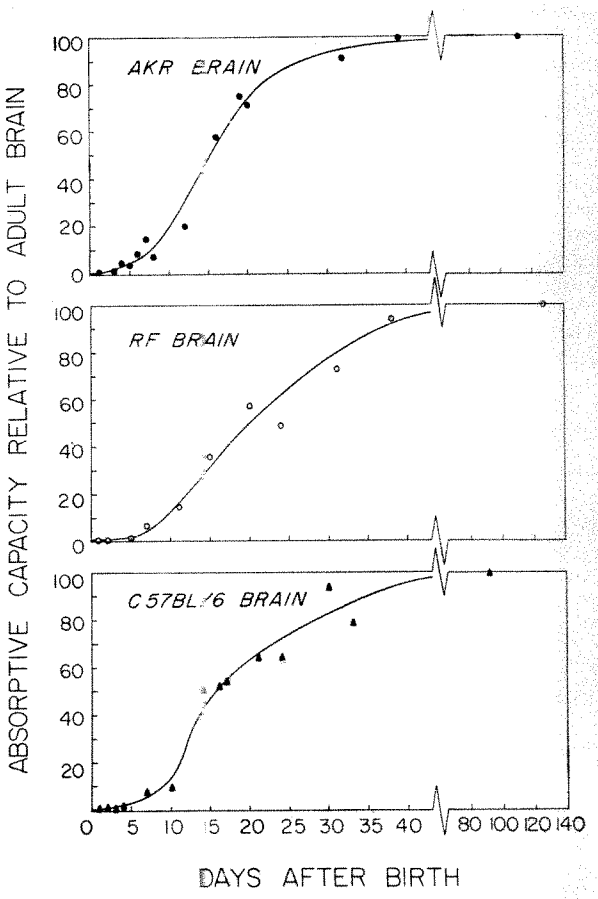

Fig. 1. Development of the θ-iso-antigens in brain of three strains of mice. The absorptive capacity per unit wet weight of brain was determined for *AKR* and *RF* mice with *C3HeB/Fe* iso-antiserum to *AKR* thymocytes, and for *C57BL/6* mice with *AKR* iso-antiserum to *C3HeB/Fe* thymocytes. Most points represent brain pooled from two mice

Previously, we reported[4] that immunological maturation of brain occurs in four strains of mice: *AKR*, *C57BL*, *ICR* Swiss and *A*. This finding has now been extended to eight additional strains: *C3HeB/Fe*, *C3H/DiSn*, *C57L*, *C57BL/6*, *C58*, *DBA/1*, *RF* and *SWR*. Neonatal brain averaged 0·8 per cent of the content of θ-iso-antigen in adult brain of these eight strains. Since no exceptions have been found, the presence of θ-iso-antigens in mouse brain, and their development from low levels at birth to high levels in young adulthood, appear to be general phenomena in mice. These results suggest the possibility that analogous iso-antigens may exist in other species including man, and may be involved in auto-immune diseases of the nervous system[1].

Comparative Investigation of Immune Globulins of Various Vertebrate Classes

During the past few years our knowledge of the immunoglobulins of man and mammals has been substantially extended. The method of making antiglobulin sera developed by Milgrom *et al.* in 1956 (ref. 1) has played a decisive part in this particular connexion. As is well known, this method makes it possible to prepare antisera which react, in addition to γ-globulins (IgG, IgA, IgM), with complemental factors, if any[2]. Since our knowledge of non-mammalian immunoglobulins is limited[3–10], I prepared (using a modification of Milgrom's method[2]) antisera to the globulins of mammals (horse, cattle, hog), birds (duck, goose), turtles (*Testudo hermanni* Gmelin), and fishes (*Cyprinus carpio* L., *Tinca tinca* (L.), *Perca fluviatilis* L., and *Ictalurus nebulosus* Le Sueur). The serum concentration used to bring about coupling with erythrocytes was chosen so that, for the mammals, only antibodies were detectable against the γ-globulins during immunoelectrophoresis. In this connexion, distinct precipitate lines of the IgG and IgM globulins were always observed. Moreover, for both horse and hog a weak line was observed corresponding to the IgA globulin. The antisera prepared against the globulins of goose and duck showed wide identity during immunoelectrophoresis. Two parallel lines were found that could be assigned to the IgG and IgM globulins (Fig. 1*A*). Clearly visible is a splitting up of the IgG line in the anodic region.

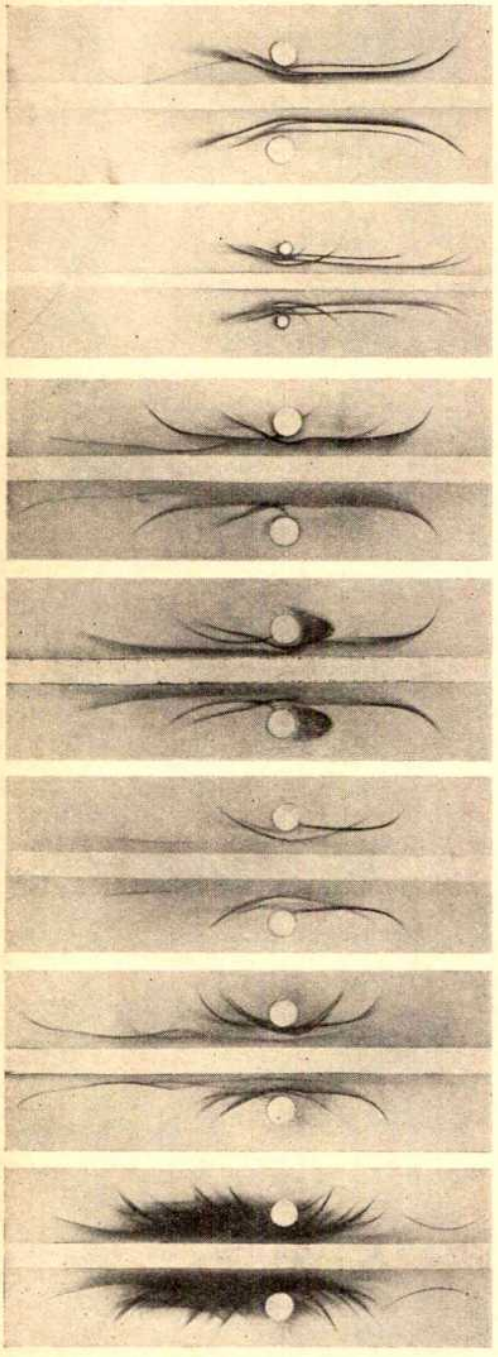

Fig. 1. Immunoelectrophoresis of 'immunoglobulins' (see text) from: *A*, duck; *B*, *Testudo*; *C*, *Cyprinus*; *D*, *Tinca*; *E*, *Ictalurus*; *F*, *Perca*; *G*, normal immunoelectrophoresis from *Perca*. Anode to the left

The immunoelectrophoretic analysis of the antiserum against turtle globulins yielded 4–5 precipitin lines (Fig. 1*B*). Of these, the IgG line shows, at both ends, a splitting that cannot be simply attributed to ageing of the serum. In addition to the typical IgM line two distinct lines were also present in the α_2 region; it is possible that these correspond to complemental factors.

Whereas the analysis of the antisera against mammalian, bird, and turtle globulins shows a certain conformity, the fish globulins differ both from the others and from one another to a considerable extent. It is true that lines corresponding to the IgG globulin are thus found for *Cyprinus*, *Tinca*, and *Ictalurus*, but they are lacking for *Perca* (Figs. 1*C*–*F*). Also, the immunoelectrophoresis with one antiserum against the complete serum proteins of *Perca* confirms the absence of a typical IgG fraction (Fig. 1*G*). Here, only a faint but entirely uniform fraction is found in the cathodic region.

The immune sera prepared using Milgrom's method precipitate for fishes, quite a large number of fractions extending into the α-globulin region, and for *Perca* and *Cyprinus* even into the pre-albumin region. Although further investigations will be required in order to clarify which of these fractions are genuine immunoglobulins, the present results already give some indication of the strong heterogeneity of the immunoglobulins for fishes.

PATHOLOGY

Leptomeningeal Sarcomata and Gliomata induced in Rabbits by Rous Sarcoma Virus

Much has been written in recent years about the ability of Rous sarcoma virus (RSV) to induce malignant neoplasms in mammals.

Heterozygotic albino mice[1], rats[1–6], hamsters[7,8], guinea-pigs[9], and monkeys[10] were found to be susceptible to the Carr-Zilber[3] strain or Schmidt-Ruppin strain of RSV (ref. 1). Recently, Bryan[11] strain and Mill–Hill (Harris)[12] strain of RSV were found to be oncogenic for hamsters[13,14].

Zilber[15] was the first to inoculate rabbits with Rous sarcoma virus. Numerous fibrous nodules and punctate haemorrhages in various organs were observed following repeated subcutaneous inoculation of Carr-Zilber strain RSV. Usually the fibrous nodules underwent reabsorption[16]. Later, Ahlström[17] subcutaneously inoculated rabbits

less than 4-weeks old with Schmidt-Ruppin[1] strain RSV. Fibrosarcoma-like tumours developed at the site of inoculation, but these regressed spontaneously after some weeks. Several of the rabbits treated in this way showed lymphogenic cysts filled with a clear fluid.

The present investigation was undertaken to determine the effects of intracerebral inoculation of RSV, Bryan[11] and Schmidt-Ruppin[1] strain, into new-born rabbits.

Both strains of RSV were prepared by the technique of differential centrifugation[18] from wing-web's sarcomata induced in 2–3-week-old white Leghorn chickens. The cell-free virus preparations were then stored in 0·153 M potassium citrate at −70° C and prepared for inoculations as previously described[8]. The titres of the final concentrations used in the inocula are shown in Table 1.

New-born rabbits (New Zealand White) were obtained from the animal production unit of the National Institutes of Health, and when they were less than 24 h old they were inoculated with 0·15 ml. of viral suspension in the mid-portion of the right cerebral hemisphere. A high degree of mortality was experienced with these animals during the neonatal period. After 3 weeks, subcutaneous fibrous nodules were discernible at the site of inoculation in the surviving animals. At this time the rabbits showed sluggishness, somnolence, lateral posture of the head and left or right hemiparesis (Fig. 1). Some animals were left to die, and some were killed in a moribund condition. Two were killed in fair condition. The results are summarized in Table 1.

At autopsy, the brain was found to be enlarged and an increase in volume of cerebrospinal fluid was noted in rabbits inoculated with the RSV (both strains). Hydrocephalus was present in most of the animals. Gross examination showed medium-size nodules scattered throughout the meninges and focal areas of malacia within the cerebral tissue. Under the microscope the superficially located nodules could be seen to consist of large elongated cells with an oval vesicular nucleus, basophilic cytoplasm with thick processes. These areas appeared to be meningeal

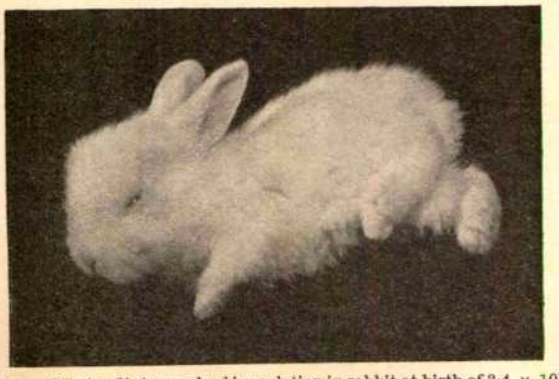

Fig. 1. Effects of intracerebral inoculation in rabbit at birth of 3·4 × 10^7 P.F.U. of Rous sarcoma virus, Schmidt-Ruppin strain. Age of the animal, 31 days. Note lump on the head at the site of inoculation, left hemiparesis and ptosis of eyelid

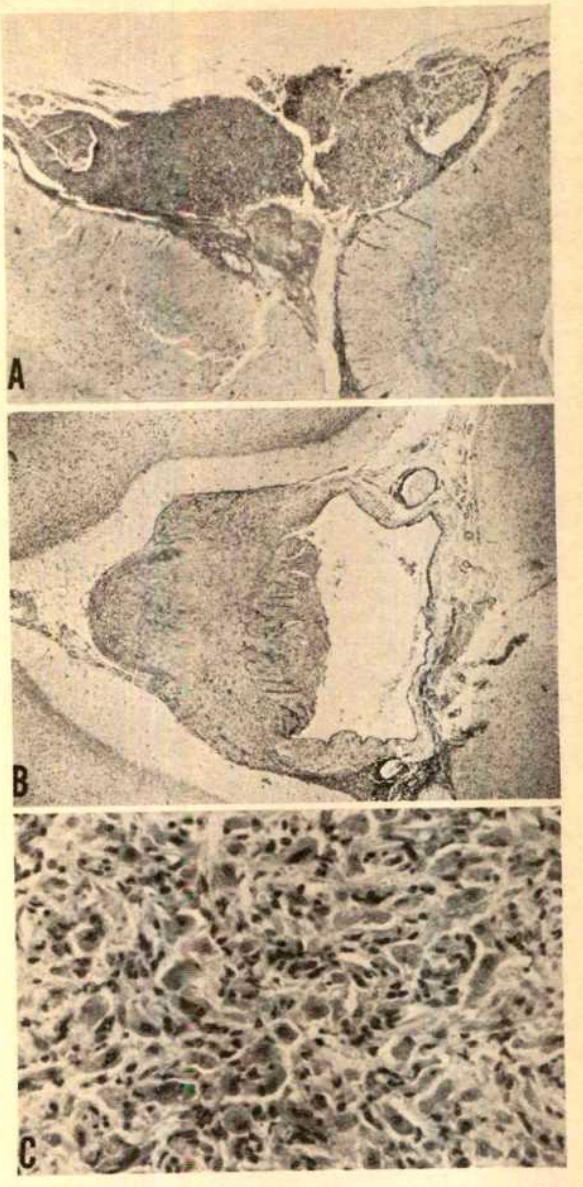

Fig. 2. (Same animal as in Fig. 1.) (*A*) Parasagittal leptomeningeal sarcoma. Haematoxylin and eosin (× *c.* 20). (*B*) Glioma in the periventricular subependymal tissue of the right hemisphere. Haematoxylin and eosin (× *c.* 17). (*C*) Cell morphology of the glioma. Haematoxylin and eosin (× *c.* 240)

sarcomata (Fig. 2*A*). The intracerebral tumours were located in the periventricular subependymal tissue and consisted of round vesicular cells, with basophilic cytoplasm, and thin fibrillar processes. These areas could be classified as gliomata (Figs. 2*B*, 2*C*).

In most of the animals small tumours were observed in the lungs, and in one instance in the liver. Control rabbits inoculated with the suspending medium alone (phosphate buffer saline) failed to show any evidence of intracranial tumours or of pathological changes after 3 months.

It has already been pointed out[8,13] that high doses of RSV are needed to produce oncogenesis in the brain of the hamster. This is also the case for the rabbit. Approximately 10^7 P.F.U. of Schmidt-Ruppin and 10^8 P.F.U. of Bryan strain RSV are needed to produce tumours in the brain of the rabbit.

The presence of tumour growth in the lungs of all rabbits, and in the liver of one treated rabbit, is probably not a case of true metastasis and may be due to viral induced neoplasms in these organs brought about by virus escaping from the brain.

The reason for the regression of the subcutaneous tumours induced in rabbits by Zilber[16] may be due to the difference in the strain of the RSV used. This was not so in the case of Ahlström's experiments[17], for he noted regression of the fibrosarcoma-like lesions of the rabbits using the Schmidt-Ruppin strain of RSV. Using the latter strain we obtained a malignant progression of the induced neoplasia which led to the death of the host. To explain these different results, it is possible that the large doses of virus used in our work may not be the only reason. The choice of the brain as a target organ may be of some importance. The induction of malignant neoplasms by RSV in rabbits has not previously been reported. Brain tumours have not been induced in this host by any virus. The use of these large animals, carrying a primary malignant tumour, should be of interest in cancer research.

Retardation of Parasitaemia, Prolongation of Life or Survival of Lactating Mice in Infections with *Trypanosoma cruzi*

Krampitz[1] found an endogenous synchronization of the propagation of host and parasite in *Trypanosoma duttoni* infections of mice. Experimental infections with *T. duttoni* at certain periods of pregnancy have resulted in an exceedingly intense and prolonged parasitaemia in mice.

Mice infected with *T. cruzi* have also shown an increase in the number of parasites during pregnancy; however, the increase was only slight compared with that in female control animals.

Lactating mice, however, display a very peculiar behaviour. Development of the parasites is retarded in them; the mice live longer or survive. When given a dosage of $1{\cdot}3 \times 10^6$ trypanosomes per mouse immediately following birth, the life of the animals is found to be about one-third longer than that of normal mice. Infection on the tenth day after birth significantly increases the time of survival. When extremely high doses of trypanosomes ($1{\cdot}3 \times 10^6$) were administered, one-tenth of the lactating mice survived. Lower doses of trypanosomes (namely 700×10^3 to 250×10^3), which would be fatal for normal mice, produce similar conditions. Here, it can be expected that up to one-half the lactating animals will survive. The results are well confirmed statistically.

White female mice, 3–4 months old (nulliparae), of the weight class 33–35 g of the strain *NMR* 1/Tübingen were used for our experiments, as well as trypanosomes of the strain *WBH* (*T. cruzi*, Wellcome Brazil–Hamburg)[2], which had been kept for approximately 1 year by mouse passages. All injections of parasites were given intramuscularly. The mouse litter was constantly adjusted to 10. Parasites obtained from venous tail blood were counted daily in a Thoma haemocytometer. Approximately 250 animals have been used so far in the experiments, which were frequently repeated. The number of mice in the various experimental groups was always kept the same (10) in order to comply with the statistical basis of the experiments.

Further experiments are being undertaken at present, in particular to clarify the cause of these strange phenomena. Therapeutical implications cannot be excluded.

RADIOBIOLOGY

Plasma Concentration and Excretion of Calcium-47, Strontium-85, Barium-133 and Radium-223 following Successive Intravenous Doses to a Healthy Man

Several investigations have been made of the turnover of radioactive calcium and strontium in man. Qualitatively their metabolism is similar, as is to be expected from their close chemical relationship, but quantitative data reveal biological discriminations which occur in certain organs. Corresponding similarities and discriminations in the turnover of barium and radium have been investigated, but experimental data refer almost entirely to laboratory animals.

In the present investigation, a healthy adult male, sixty years old, was given not only barium and radium but also calcium and strontium so that the metabolism of all four alkaline earths could be compared in the same individual. By this means, biological variation between different individuals was eliminated. Each radioactive isotope was given intravenously on a separate occasion (Table 1), but all four were administered within a 10-week period to minimize any possible temporal changes in turnover. The present preliminary report gives the results for the plasma concentration and excretion following the four successive intravenous injections of the separate radioactive isotopes.

A weighed portion from a solution of the respective carrier-free radioactive solution was made up to 10 ml. in isotonic saline. 4 ml. of a sterile solution were injected into the antecubital vein of the right arm and the remainder was used for the preparation of radioactive standards. Urine and faeces were collected and serial 20-ml. blood samples were taken by veni-puncture from the left arm at 10 min, 3 and 12 h and about 1, 2, 4, 6 and 8 days after each intravenous dose.

For ^{47}Ca, ^{85}Sr and ^{133}Ba, the γ-ray intensity in the principal photopeak (Table 1) was measured with a scintillation γ-ray spectrometer by comparing the counting-rate in the peak with that from a standard solution. In the case of ^{223}Ra, the method of assay for solutions of faecal ash was essentially the same, but in samples of low activity, for example, in plasma, the total α-particle activity in a chemically separated fraction was compared with that from a standard.

The results obtained for the plasma concentrations of the separate radionuclides up to 8 days after injection are

Table 1. Characteristics of Injected Isotopes

Isotope	Half-life	Radiation emitted	Principal γ-ray energy (MeV)	γ-ray abundance (%)	Intravenous dose (μc.)	Date of injection
^{47}Ca	4·7d	β-γ	1·31	77	1·94	26.2.65
^{85}Sr	65·0d	γ	0·51	100	0·54	9.2.65
^{133}Ba	7·5y	γ	0·36	70	2·25	12.1.65
^{223}Ra and daughter products	11·7d	$\alpha\beta$-γ	0·27	~20	0·72	23.3.65

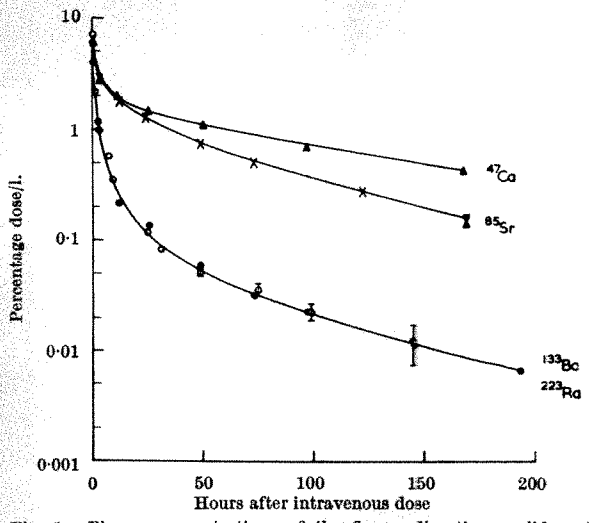

Fig. 1. Plasma concentrations of the four radioactive nuclides at various times after the respective intravenous dose

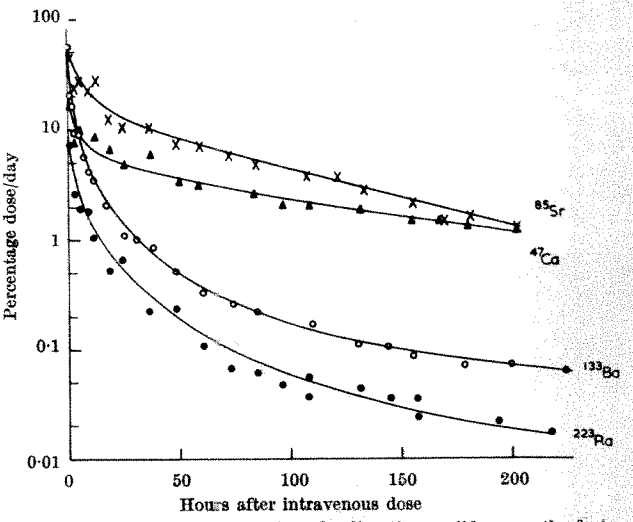

Fig. 2. Rate of urinary excretion of radioactive nuclides over the first 8 days after the respective dose

shown in Fig. 1. The concentrations of ^{133}Ba and ^{223}Ra were indistinguishable over the period of measurement and after a few hours they were more than an order of magnitude less than those for ^{85}Sr and ^{47}Ca.

It is of special interest to note that 8 years ago plasma concentrations of ^{85}Sr were measured up to 50 h after an intravenous dose in the same experimental subject[1]. The results of these earlier measurements are in good agreement with the present ones for which the precision was much greater.

The present values for the plasma concentrations of ^{223}Ra are in general agreement with those observed by Atherton *et al.*[2] following an intravenous dose to a chronically sick man forty-two years old. Bauer, Carlsson and Lindquist[3] measured the plasma concentrations in a woman twenty-five years old following intravenous injections of ^{45}Ca and ^{140}Ba. The fall in plasma concentration with time was in general agreement with the results for ^{47}Ca given in Fig. 1, but for ^{140}Ba corresponding values were about three times greater than the present ones for ^{133}Ba. This discrepancy may well be due to difficulty in the estimation of the β-particle contribution of ^{140}Ba in a mixture of ^{45}Ca, ^{140}Ba and ^{140}La.

The urinary output rate for the four separate radionuclides over the first 200 h after the dose is shown in Fig. 2. Values are shown in Table 2 of the renal clearance, defined here as the ratio of urinary output rate to the contemporary plasma concentration. The renal clearance for strontium was 3·2 times that for calcium in good agreement with earlier measurements on the same man[4] and with clearance ratios reported for different subjects[4,5]. So far as we know, the results for the renal clearance of ^{133}Ba and ^{223}Ra (mean values 10·2 and 3·4 l. per day, respectively) are the first measurements to be reported for man. There is some evidence of a fall in the renal clearance of both ^{133}Ba and ^{223}Ra after the first 24 h (Table 2). This fall could be due to a change in the ion-binding of these nuclides in plasma.

Total excretion (urine plus faeces) is shown in Fig. 3. This was ^{47}Ca < ^{85}Sr < ^{133}Ba and ^{223}Ra; about 85 per cent of the injected dose of the latter pair were excreted in the first 8 days. Values are also given for the ratio of the total faecal to the total urinary output in the first 8 days after the dose. These results show that gastro-

Table 2. RENAL CLEARANCE (L. PER DAY) OF ^{47}Ca, ^{85}Sr, ^{133}Ba AND ^{223}Ra AFTER INTRAVENOUS DOSE

Hours after dose	^{47}Ca	^{85}Sr	^{133}Ba	^{223}Ra
2	3·7	12·4	10·6	3·1

intestinal clearance of the intravenous dose predominates for ^{133}Ba and especially ^{223}Ra.

A further report will appear elsewhere giving additional results, particularly of the retention measurements. These are still in progress for ^{85}Sr and ^{133}Ba. We expect reliable estimates of the body content of the former isotope to be obtained over the next year and of the latter over several years.

We thank Mr. F. J. Sandalls and Mr. A. Holmes of the Health Physics and Medical Division, Atomic Energy Research Establishment, Harwell, for their help in the assay of ^{223}Ra in various samples. The ^{223}Ra was separated from a pure source of ^{227}Ac at the Radiochemical Centre, Amersham.

Formation of Ribonucleic Acid during the Recovery of the Deoxyribonucleic Acid Synthetic System of Bacteria damaged by Ultra-violet Light

A requirement for RNA and protein synthesis in recovery of the DNA synthetic system of *Escherichia coli* damaged by ultra-violet light (UV) has been demonstrated[1–4]. At that dose of ultra-violet light producing the maximum possible delay in DNA synthesis without non-restorable inactivation, an approximate doubling of RNA occurs before initiation of DNA synthesis[4]. If chloramphenicol, an antibiotic which blocks protein synthesis, is added before the doubling of RNA, DNA synthesis proceeds, after the completion of the restoration period, at a reduced, non-accelerating rate directly related to the increase in RNA between the time of exposure to ultra-violet light and the time of adding chloramphenicol[4].

The dye, acriflavine, at appropriate concentration blocks DNA synthesis in the UV-damaged cell but allows formation of RNA in limited amount and at a reduced rate[4,5]. The RNA synthesized is primarily the soluble variety with density gradient sedimentation characteristics comparable with rapidly labelled or messenger RNA; little RNA is incorporated into ribosomal fractions[6]. Acriflavine was added to a UV-exposed culture of *E. coli* (strain *WP2*) after different periods of post-irradiation incubation at 37° C. The results of this experiment are shown in Fig. 1. It was observed that the rate of synthesis of DNA in acriflavine increases with the duration of the post-irradiation restoration period before addition of the dye, as was found with chloramphenicol[4]. Restitution of DNA synthesis is correlated with recovery of capacity for RNA synthesis in the presence of the dye equivalent to the UV-exposed culture incubated without the dye (Table 1) and with the formation of the 30*S* and 50*S* ribosomal fractions[6]. A comparable pattern of effect has been found for chloramphenicol on RNA synthesis (but not on formation of ribosomal fractions) in UV-exposed cultures. These results suggest that restorative processes in the UV-exposed cell restitute some damage, presumably to the DNA, with which the dye interacts to block DNA synthesis and the synthesis of the RNA involved in formation of the ribosomal fractions. It would appear that, for restoration of synthesis to occur, some synthetic event blocked by acriflavine, which is located randomly in the population in regard to time elapsed from initiation of the restorative process, must occur before addition of the dye. That this event involves protein synthesis is suggested by the comparable results with chloramphenicol[4]. Thus, when the dye is added subsequent to the synthetic event for a given bacterium, synthesis of RNA involved in formation of ribosomal fractions proceeds (Table 1) but initiation of DNA formation requires a restorative period subsequent to addition of the dye (Fig. 1).

Table 1. Effect of Acriflavine, added after Different Periods of Incubation following Exposure to Ultra-violet Light, on Subsequent RNA Synthesis with *E. coli* Strain *WP2*

No UV, + AC	1·62	2·14	2·63	—	—	—	—

* See the legend for Fig. 1 for details of this experiment. The cultures were exposed to ultra-violet light (45 sec) and then incubated at 37° C. At the indicated times after exposure to ultra-violet light, acriflavine (AC) was added and incubation continued (please read across). The culture labelled 'No AC' had no acriflavine added. The culture labelled 'No UV, no AC' was an unirradiated control culture with no acriflavine in the incubation medium. The culture labelled 'No UV, + AC' was an identical culture with acriflavine in the incubation medium.

† Relative amount of RNA at the time of sampling after the indicated period of incubation over that at the time of exposure to ultra-violet light. This amount (1·0) was 150 μg per ml. of culture.

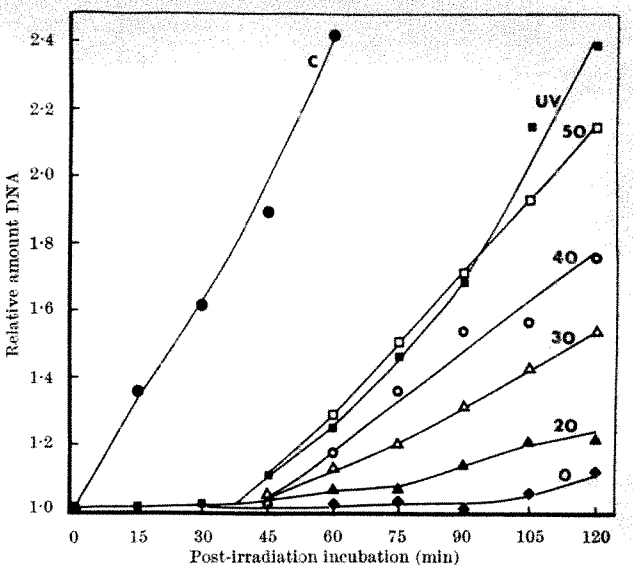

Fig. 1. DNA synthesis in acriflavine added after different periods of incubation at 37° C after exposure to ultra-violet light of a culture of *E. coli* strain *WP2* (tryptophan requiring). The exposure was for 45 sec at a dose rate of 10 ergs/mm²/sec as measured by a Hanovia ultra-violet meter at the position of the cells. The time of addition of acriflavine (0·5 μg/ml.) to each culture after exposure to ultra-violet light is denoted (in minutes) by the number labelling each curve. The curve labelled '*UV*' denotes a culture exposed to ultra-violet light and incubated without addition of acriflavine. The curve labelled '*C*' represents an unirradiated control culture incubated without addition of acriflavine. Acriflavine at the concentration used does not significantly inhibit the formation of DNA in an unirradiated culture. The amount of DNA at the time of initiation of incubation in 1 ml. of the culture was 20 μg. The techniques used have been described[7]. All incubations were in minimal medium supplemented with 20 μg per ml. of L-tryptophan

The synchrony of initiation of DNA synthesis in UV-exposed cultures[4] could be explained if it were assumed that the completion of a sequential cycle of repair of the damage done by the ultra-violet light to the bacterial chromosome is necessary for resumption of DNA synthesis. Evidence has been presented that the decrease in rate of DNA synthesis caused by addition of chloramphenicol prior to complete recovery involves the inhibition of synthesis of part of the DNA[4]. The results with chloramphenicol (and acriflavine) could be explained if at some site on the circular chromosome, randomly situated in the bacterial population in relation to the site of initiation of restoration of damage done by the ultra-violet light, protein synthesis were necessary for the continuation of restoration. Thus, only when the restorative process has passed the chromosomal site requiring protein synthesis by the time of chloramphenicol addition would repair of the chromosome be continued to completion and the initiation of DNA synthesis occur.

The suggestion has been made that complementary RNA formation on the DNA template is involved in restitution of the UV-damaged DNA synthetic system[4,7]. That RNA synthesis (but not protein synthesis) is required for restoration of the UV-damaged DNA synthetic system subsequent to the requirement for protein synthesis already described can be supported by the following experiment in which chloramphenicol and 6-aza uracil are added to UV-exposed cultures of *E. coli* after 30 min of post-irradiation incubation and removed after 50 min (Fig. 2). Chloramphenicol (which inhibits protein but not RNA synthesis)[8,9] in a UV-exposed culture during this period allows completion of restoration, as indicated by initiation of DNA synthesis at the same time as observed with a UV-exposed culture incubated without chloramphenicol. However, 6-aza uracil (which inhibits both RNA and protein synthesis in bacteria)[3,10] in a UV-exposed culture[3] during this period results in a delay in initiation of DNA synthesis for 10 min after removal of the bacteria from the analogue, a period equal in duration to that period of time between addition of the analogue and the initiation of DNA synthesis as observed with UV-exposed cultures

Table 2. DELAY IN DNA SYNTHESIS WITH UV-EXPOSED *E. coli* STRAIN *WP2* INDUCED BY DIFFERENT PERIODS OF INCUBATION WITH 6-AZA URACIL DURING THE RESTORATION PERIOD

Time of addition of 6-aza uracil (min)*	0	10	20	30	40
Projected time of initiation of DNA synthesis†	72	66	58	51	41

* See the legend to Fig. 2 for details of this experiment. The cultures were exposed to ultra-violet light (45 sec) and incubated at 37° C. 6-aza uracil was added at the indicated times after exposure and incubation continued. The bacteria were removed from this medium by filtration after 40 min of post-irradiation incubation and resuspended for further incubation in fresh medium free of the analogue.

† Determined by projection to a relative DNA concentration of 1·0 (see Fig. 2) of a straight line through four points representing relative amounts of DNA determined at 10-min intervals of sampling after initiation of measurable DNA synthesis. The rates of DNA synthesis observed in these cases were comparable with that observed for the 6-aza uracil incubated culture as reported in Fig. 2.

incubated without the analogue. That the increased delay in DNA synthesis caused by prior incubation with the analogue is related in duration to the period of interruption of the post-irradiation recovery process is demonstrated by the results of another experiment (Table 2). In this the analogue was added after different periods of incubation after exposure to ultra-violet light and removed at the time of initiation of DNA synthesis in the UV-exposed culture incubated without the analogue. That chloramphenicol blocks the formation of ribosomes but allows formation of RNA to occur[8,9] suggests the possibility that the RNA which is involved in restoration of the UV-damaged DNA synthetic system is complementary RNA formed at the site of repair. The assumption that a 'node' of RNA synthesis on the DNA template at the time of exposure to the ultra-violet light, randomly situated in relation to the origin of the chromosome, is the site of post-irradiation initiation of the RNA synthesis involved in restoration and that protein synthesis is required for this node to pass the chromosomal origin (or some other site) would be in harmony with the foregoing observations. The results with acriflavine (Table 2) suggest that this protein formation somehow triggers the formation of ribosomal RNA.

The nature of the molecular mechanism by which RNA synthesis effects restoration of the UV-damaged DNA synthetic system cannot be defined at the present time. It has been suggested that such complementary RNA might function in some undefined manner in the restitution of the DNA after enzymatic excision of a region of the DNA strand containing a UV-induced lesion, such as the thymine dimer[4]. This hypothesis would imply that the formation of DNA strands in the region left after excision of the thymine dimer region occurs sequentially along the chromosome and is dependent on RNA synthesis. Evidence for such synthesis of DNA during the restoration period has been presented[11]. However, the fact that restoration of damage done by ultra-violet light occurs in a thymine-requiring strain deprived of thymine during the restoration period[1–3] casts doubt on the assumption that restoration requires sequential resynthesis of DNA in the excised regions of the chromosome during the restoration period. This would not preclude resynthesis of the excised regions on addition of thymine and initiation of DNA synthesis, as a result of the previously completed restoration process involving RNA synthesis. The suggestion has been put forward that complementary RNA derived from the opposite DNA strand functions as a template in by-passing sites of UV-damage to the DNA strand[7].

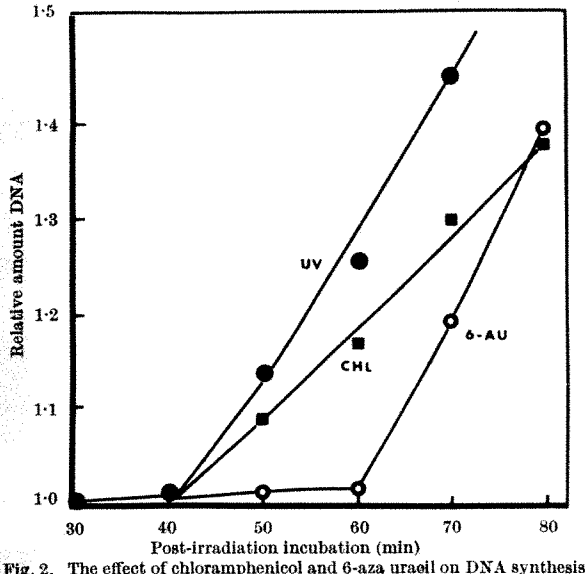

Fig. 2. The effect of chloramphenicol and 6-aza uracil on DNA synthesis in UV-exposed cultures of *E. coli* strain *WP2* (tryptophan requiring). These antimetabolites were added to separate UV-exposed (45 sec) cultures after 30 min of post-irradiation incubation in tryptophan-containing minimal medium at 37° C. The resulting concentration of chloramphenicol (*CHL*) was 40 μg per ml. and that of 6-aza uracil (*6-AU*) was 50 μg per ml. The curve labelled '*UV*' denotes DNA synthesis in a UV-exposed culture incubated without addition of either of the antimetabolites. After 50 min of post-irradiation incubation, the three cultures were separated from their growth medium using membrane filters, washed with warm (37° C) tryptophan-supplemented minimal medium and resuspended to the same volume in the same warm medium. This operation took less than 2 min. Incubation was then continued. The techniques used have been described[7]. The amount of DNA in 1 ml. of culture at the time of initiation of incubation was 24 μg

These results suggest the possibility that complementary RNA is an essential component of the DNA synthetic system in the unirradiated bacterial cell and that post-irradiation RNA formation is necessary for repair or replacement of sites damaged by ultra-violet light in this RNA. This possibility might underlie the observation[4] that a doubling of RNA occurs before initiation of DNA synthesis in cultures exposed to that dose of ultra-violet light which produces maximum delay in initiation of DNA synthesis without non-repairable inactivation. It could be assumed that at this dose almost complete replacement of the RNA involved in restoration is necessary. The reduced duration of the delay in initiation of DNA synthesis with lower doses of ultra-violet light[4] would be related to the possibility that with lower doses of ultra-violet light, the RNA involved need only be partially replaced and that the sequential restoration mechanism is able to pass rapidly over regions of undamaged RNA. All these considerations imply that complementary RNA formation on the DNA template encompasses (or controls) gross replication of RNA in the cell. The concept that prior gross RNA formation somehow limits subsequent DNA synthesis in the growth cycle of the bacterial cell is supported by a recent investigation[4,12]. Thus, involvement of protein formation in initiation of the cycle of DNA synthesis may be indirect and dependent on the necessity of protein formation for continuation of RNA synthesis past the chromosomal origin and for the formation of ribosomes.

Some implications of these findings for the understanding of mutation in bacteria induced by ultra-violet light will be presented elsewhere[6,10].

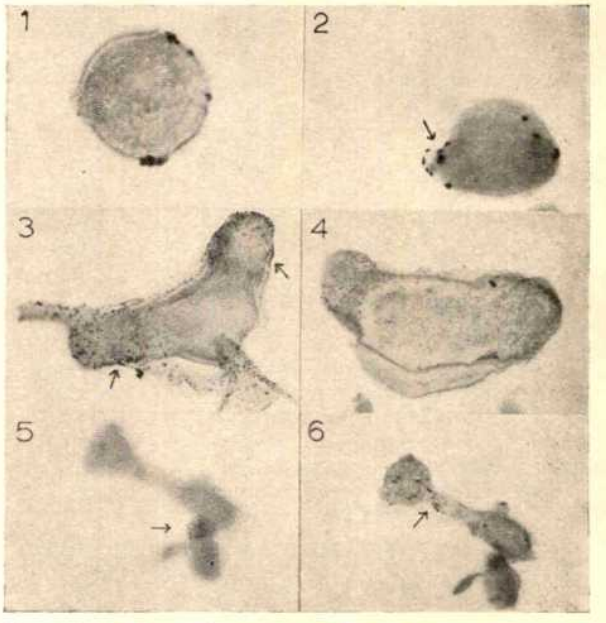
BIOLOGY

Myo-inositol-2-t Incorporation by Germinating Pollen

Pollen of pear (*Pyrus communis*) germinated *in vitro* in 10^{-3} M *myo*-inositol-2-*t* rapidly incorporates label into its 70 per cent ethanol-insoluble polysaccharides[1]. Analysis of pectinase hydrolysates recovered nearly all this label in D-galacturonic acid and L-arabinose residues. Other investigations[2,3] have shown that this conversion is highly specific and that the original carbon sequence in inositol is conserved. Hexose constituents present in these 70 per cent ethanol-insoluble pollen residues, principally D-glucose and D-galactose, are essentially unlabelled.

This communication offers autoradiographic evidence to show that *myo*-inositol-2-*t* taken up by germinating pollen and incorporated into alcohol-insoluble tissue residues is initially localized in the pore region of the pollen grain; with germination the label appears in pollen tube membranes.



Pollen of *Oenothera organensis*, from the Botanical Garden, University of California, Berkeley, and of *Pyrus communis* var. 'Packham Triumph', from Mina T. Firman Co., Chelan, Washington, was used in these experiments. In a typical run, *Pyrus* anthers collected during the spring of 1963 and stored over desiccant at $-15°$ C for 5 months were returned to room temperature and shaken in a small straight-walled polyethylene container. The pollen grains clung to the plastic container walls and the anther residue was discarded. Pollen samples of about 50 mg were scraped from the plastic container walls and sprinkled on the surface of a solution in a 4·5-cm diam. Petri dish containing 0·4 M sucrose, 10^{-3} M calcium phosphate (*p*H 7), 10^{-3} M sodium borate, and 4×10^{-3} M *myo*-inositol-2-*t* (34 μc./mg). Incubation at 26° C for 0·5–3 h resulted in germinated pollen grains with tubes up to 100μ in length. Following incubation, each portion was fixed in 15 ml. of a 3 : 1 mixture of ethanol and glacial acetic acid. Within 30 min, most of the pollen settled to the bottom and excess fixative, together with most of the labelled media, could be drawn off with a Pasteur pipette. Fixed tissues were re-suspended in fresh fixative and allowed to settle several times to remove all traces of soluble radioactivity. After the final wash, the pollen was transferred to paraffin for sectioning.

Under Kodak 'Safelight' filter Wratten 1, sections were laid on pre-warmed slides coated with photographic emulsion (plate type *V*1060, Kodak, Ltd., England), covered with a thin sheet of 'Teflon', and pressed firmly against the emulsion by applying light pressure with a hand roller. Slides were then stored in light-tight boxes for 2–4 weeks. After storage, each slide was dipped into 1·25 per cent cellulose acetate emulsion and drip-dried at least 3 h to secure the pollen sections in place during subsequent steps of photographic development and staining[4]. Stained, developed slides were examined microscopically for comparison of morphological features and occurrence of silver grains sensitized by tritium in the film directly beneath the sections. Photographic records were made with a 'Polaroid-Land' camera using 'Polapan' 200 type 42 film.

In Figs. 1 and 2, pollen of *Oenothera*, grown for 30 min at 26°, reveals a highly localized distribution of tritium in pore regions. All three pores of *Oenothera* incorporated tritium, although the planar sections seen in these figures prevent one from viewing the third pore. Similar results were obtained with pollen of *Pyrus*. Evidence that considerable metabolism occurs in pollen grains even before tubes become microscopically visible has been obtained with *Petunia* pollen[5]. Heslop-Harrison[6] has published interesting electron micrographs in which he notes a distinct modification of the plasmalemma underlying the pore area. As these areas develop during the formation of pores, an underlining plate of endoplasmic reticulum forms. There is no wall growth over these pore areas during subsequent development and maturation of the pollen grain. Electron micrographs prepared by M. Ledbetter (personal communication) also clearly reveal the presence of a reticulate plasma membrane which penetrates the intine layer in the pore region of mature *Saintpaulia* pollen. The present observations merely reveal incorporation of tritium into tissue structures resistant to the extractive procedures used during tissue fixing and staining. However, one can assume from our previous investigations that the structures involved include labelled pectic substance derived from metabolism of *myo*-inositol-2-*t*.

As germination proceeds and the tube elongates, tritium localizes in the non-extractable portions of the tube membrane (Fig. 2) and accumulates in an annular pattern about the circumference of the pore at the tube base. In Figs. 2 and 3, sections through sucrose-germinated pollen of *Oenothera* reveal a concentration of tritium (indicated by arrows) coincident with the basal wall regions a short distance beyond the point where the tubes emerge from the pore. Similar observations made in *Pyrus* pollen can be seen in Figs. 5 and 6, in which the same view is presented at two focal depths. In Fig. 5, a high concentration of tritium is revealed by oblique section through the base of one pollen tube, while in Fig. 6 a second pollen tube in approximately longitudinal section reveals the same pattern close to the juncture of tube and pore. These accumulations of tritium might represent regions in which pectin is deposited at the time of germination. Alternatively, these accumulations might result from pectin formation in the pore surface prior to germination, in which case eruption of the pore membrane and elongation of the pollen tube would create an annular ring of tritium-labelled tissue about the pollen tube at its basal end.

In one experiment with pollen of *Oenothera* and *Pyrus*, sucrose was replaced with three molar equivalents of D-glucose in the germination medium. As seen in Fig. 4, non-extractable tritium from *myo*-inositol-2-*t* metabolism appeared throughout cytoplasmic regions, especially in

Figs. 1–6. Fig. 1. Autoradiograph of a fixed section of *Oenothera organensis* pollen which has been germinated at 29° C in a solution containing 0·4 M sucrose, 0·001 M calcium phosphate (*p*H 7·0), 0·001 M sodium borate and 0·004 M *myo*-inositol-2-*t* (34 μc./mg) for 30 min. Fig. 2. Same as Fig. 1 but germinated about 50 min. Fig. 3. Same as Fig. 1 but germinated about 90 min. Fig. 4. Same as Fig. 3 except sucrose was replaced by 1·2 M D-glucose. Fig. 5. Same as Fig. 1 but with *Pyrus communis* pollen germinated for 60 min. Fig. 6. Same section shown in Fig. 5 but taken at a different focal depth

the regions behind each pollen tube tip. Glucose, but not sucrose, is readily utilized by germinating *Pyrus* pollen for biosynthesis of pectic substance (unpublished observations). In the present experiment, it appears that glucose does not interfere with movement of *myo*-inositol into cytoplasmic regions or incorporation of *myo*-inositol into cytoplasmic structures which resist extractive procedures used during fixation but does prevent subsequent mobilization of tritium-labelled metabolites into cell-wall structures. Additional experiments are necessary before detailed evaluation of the glucose effect can be attempted.

In summary, autoradiographic experiments in which pollen grains were germinated in a sucrose-rich media containing *myo*-inositol-2-*t* reveal a highly localized pattern of tritium incorporation into non-extractable tissue structures in the pore region shortly after the pollen is placed in the labelled medium. During subsequent tube development, tritium is incorporated into structures of the walls and membranes of fixed pollen tube sections. From related investigations, it appears that these tritium accumulations represent regions of deposition of pectic substances.

An Adaptive Butyrase Enzyme System in the Alga *Prototheca zopfii*

Anderson[1] reported that *Prototheca zopfii*, which is a colourless alga, was able to assimilate most of the monosaccharides, and all the fatty acids with the exception of formic, isovaleric and pyruvic acids. Pyruvate could, however, become assimilated if the *p*H were lowered to 4·5, and this also affected the rate of oxidation of the carbon energy source.

During confirmation of this work, *P. zopfii* (Strain 263/5) from the National Collection of Algae and Protozoa, Botany School, Cambridge, was grown in liquid culture consisting of a carbon energy source at a dilution of 0·1 per cent in a basal medium suggested by Whickerham[2]. Glucose, ethanol, and the sodium salts of lactic and butyric acid were investigated. The inoculum was derived from a culture adapted to glucose utilization by continual sub-culture on a 0·1 per cent glucose supplemented (Whickerman, 1951) medium. All cultures were incubated at 25° ± 0·5° C and aeration improved by sloping the tubes containing 5 ml. of medium to angle of 10° from the horizontal. Preparation of the inoculum was carried out by centrifuging out the cells from liquid culture at 4,000 r.p.m. for 20 min and washing the cells with sterile distilled water. 10×10^5 cells were used as the inoculum for each culture. Growth was estimated using an EEL nephelometer and obtaining cell population by comparison of the readings to a standardized graph relating nephelometer readings to gross cell density in the culture. All the results for the four carbon substrates used are recorded in Fig. 1.

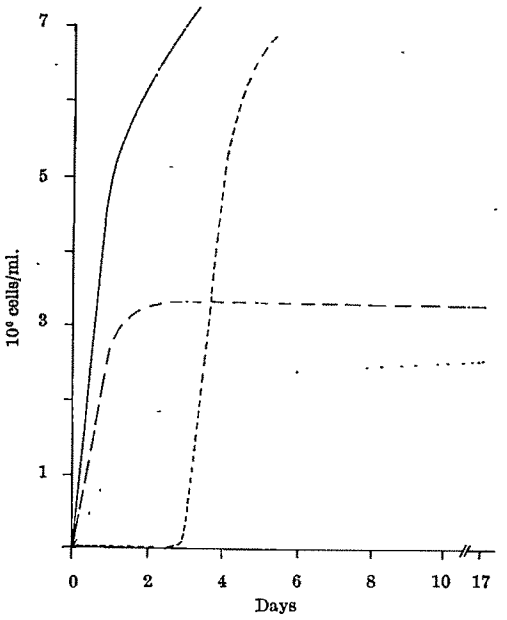

Fig. 1. Graphical representation of the growth of *Prototheca zopfii* on four carbon substrates: glucose (——), ethanol (– · – · –), lactate (. . . . .), and butyrate (– – –) when incubated at 25° C

Glucose, ethanol and lactate were all utilized immediately, although each with a different intensity of final cell production. Since *P. zopfii* was adapted to glucose and grew immediately and assimilated ethanol and lactate, this indicated the presence of constitutive enzyme systems for these two organic compounds. For butyrate, there was a lag period of 3 days before growth commenced. Growth was then as rapid as for the utilization of glucose, indicating that this strain of *P. zopfii* has a very efficient adaptive butyrase enzyme system.

Repellency of the Mandibular Gland Scent of Worker Honey Bees

The mandibular glands of worker honey bees secrete 10-hydroxy-2-decenoic acid, the chief lipoid component of larval food[1,2], but although this substance is odourless, the secretion as a whole has a strong smell resembling that of the mould on blue-veined cheese. It is now shown to be repellent to foraging bees.

A 50 × 18 mm glass specimen tube containing sucrose syrup was exposed in an apiary and a few bees trained to visit it. When sufficient bees were visiting the tube it was replaced by three clean tubes symmetrically arranged on a table that could be revolved. Following Ribbands[3], the repellency of a substance was tested by placing it in two of the tubes and a control substance in the third. The table was turned frequently so that no tube had a constant position relative to the general surroundings. Each bee that landed was immediately driven off. A bee landing on the tube with the control substance was counted as positive and one landing on either of the tubes with the test substance negative. Each test was con-

tinued until either the number of positives exceeded the number of negatives by 5, which showed preference for the control tube ($P = 0.031$), or the number of negatives exceeded the number of positives by 6, which signified nothing. The materials used were crushed heads of foraging bees in ethylene glycol, crushed thoraces of the same bees in ethylene glycol, and ethylene glycol alone. Solution in glycol was necessary to retard evaporation of the scent, which otherwise became imperceptible in a few minutes. In other experiments the number of bees landing on each of a pair of tubes was counted until a total of ten landings had occurred; then a fresh pair of tubes was provided and the experiment repeated. Tests were made with clean empty tubes, clean tubes containing sucrose syrup, tubes from which bees at another feeding place had been actively taking syrup and tubes that these other bees had emptied of syrup and, though still visiting, were leaving, unsatisfied. Each bee that landed on a tube during the tests was immediately driven off, and if the tube was a clean empty one it was replaced by another.

Tubes with thoraces were preferred ($P < 0.001$) to tubes with heads (Table 1); this was because the heads were actually repellent and not merely less attractive than the thoraces, as tubes with glycol alone were preferred ($P < 0.001$) to those with heads. The mandibular-gland scent was fairly certainly responsible for the repellency of the crushed heads, as no other part of the head has a readily noticeable smell. Tubes that bees had emptied of syrup and were leaving, unsatisfied, were more attractive than tubes from which bees had been actively gathering syrup ($P < 0.02$, Table 2). It is unlikely, therefore, that bees warn others away from an exhausted food source by depositing mandibular gland scent on it.

Table 1. Repellency of Mandibular Glands

No. of bees landing on tubes in each test. (Nos. in parentheses are for two tubes)

Contents of tubes	Test No. 1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
10 crushed heads in ethylene glycol	(8)	(4)	(1)	(1)	0	0	0	0	1	(10)	(1)	(0)	(0)	(0)	(1)	(1)	(1)
10 crushed thoraces in ethylene glycol	13	9	6	6	(6)	(6)	(6)	(6)	(7)								
Ethylene glycol alone										15	6	5	5	5	6	6	6

Table 2. Absence of Repellency at Exhausted Food Source

Tube *A*	Tube *B*	Mean of $(a-b)$*	*S.E.* of mean	No of tests
Clean, containing syrup	Clean, empty	1·00	0·72	12
Containing syrup on which bees had been feeding	Clean, containing syrup	0·80	0·79	10
Emptied of syrup by bees; bees had still been landing but were finding no syrup	Clean, empty	5·22	0·69	13

* a = No. of landings on A. b = No. of landings on B

The repellency of honey-bee mandibular-gland scent to foragers is surprising; the stingless bee, *Scaptotrigona postica*, marks points along routes to food sources with its mandibular gland secretion[4], which is physically similar to that of honey bees[5], and in males of many bee species the secretion is a sexual attractant[6]. Foraging bees usually have more secretion in their mandibular glands than bees taken from the hive[7], but this is probably evidence of diminished use rather than more active secretion, as it is the younger bees that feed the secretion to larvae, and the older ones (that is, those most likely to be foraging) have smaller secretory cells in their glands[8]. Probably the scent is present in newly discharged larval food and soon evaporates; if so, it may deter nurse bees from giving more food to larvae that have just been fed. Maschwitz[9] found that mandibular-gland secretion evoked an aggressive reaction from bees at a hive entrance, and Shearer and Boch[10] obtained a similar reaction with 2-heptanone, which they had identified in the secretion. Mandibular-gland scent is much less effective in producing hostility than the scent that is contained in a fold in the membrane at the base of a bee's sting[9], but it seems likely that it does play some part in colony defence. Possibly its main function is to repel robbers; this could explain its repellency to syrup-collecting bees.

An Estuarine Fauna in a Freshwater Lake in South Africa

An expedition from the Department of Zoology and Entomology, Rhodes University, recently visited Lake Sibayi in Northern Zululand, Natal. The lake is completely separated from the sea by a line of forest-covered sand-dune which is 600 ft. high at the highest point. During July the lake water was homogeneous throughout, thus there was no stratification with regard to temperature (17°–18° C) or chlorides. The chloride content of the water in July, which is the dry season, was 135 p.p.m. This is high, and the lake can be regarded as being chloride-enriched. The source of chloride is possibly the cyclical salt carried in the air from the sea and precipitated in the basin, the sea being only half a mile from the lake at its nearest point. However, assuming that the chloride is derived from the sea and that the salts present in the lake are in the same proportion as in sea-water, the salinity would be in the region of 0·25 parts per thousand. This is extremely low and the lake must perforce be regarded as a freshwater environment.

A normal freshwater fauna was found, as typified by chironomids, oligochaetes, freshwater pulmonates (*Bulinus*, *Biomphalaria*, *Lymnaea*) and the prosobranch *Melanoides*, freshwater fish (*Clarias*), mayflies, Odonata, belostomatids, dytiscids and hydrophyllids. In addition there is a typical estuarine component as shown by amphipods, tanaids, isopods, polychaetes and both adults and zoeae of *Hymenosoma orbiculare* Desm. The amphipods were found bearing well-developed eggs. Tinley[1] has recorded the estuarine fish, *Gilchristella aestuarius* (Gilchrist and Thompson), and *Atherina breviceps* Cuvier.

Of the animals so far identified, the crab *Hymenosoma orbiculare*, an isopod *Cyathura carinata* (Kröyer) and two of the four species of amphipods have been reported from Natal estuaries[2,3].

The discovery of estuarine animals in a freshwater lake requires an explanation. Clearly the presence of such a fauna indicates an estuarine origin for Lake Sibayi. Bathymetric soundings in the lake indicate the presence of a north–south running trough with a so far recorded maximum depth of 38 m. The floor of this trough is at least 30 m below present sea-level and this indicates that its formation occurred at a time when the sea was at a lower level than it is at present. This hypothesis is supported by geological evidence of a lowered sea-level of 30–40 m during a Pleistocene glacial phase[4]. After the sea-level rose again the mouth of the estuary closed to form the present lake.

We consider that this is a unique situation not previously described in South Africa and that the estuarine animals found in Lake Sibayi represent the remnants of an estuarine fauna. From this the question arises whether the fauna has slowly adapted to increasingly freshwater conditions or whether the species found can normally live in fresh waters but are excluded by other factors. Experi-

mental investigations in an endeavour to solve this problem are being carried out in our laboratories.

Composition of the Blood in Onychophora

The primitive terrestrial arthropods of the Class Onychophora are of especial zoological interest. As comparatively little is yet known of their physiology it seems worth recording some measurements of the blood ion-levels in *Peripatopsis moseleyi* and also the composition of a satisfactory physiological saline based on these ion-levels (Tables 1 and 2).

Table 1. Concentration of Ions in Blood of *P. moseleyi* in m.equiv./l.

	Na	K	Ca	Mg	Cl
Average of 7 animals	109*	5·6*	< 20†	< 1 not detected	—
Individual specimens	94·5	3·46	—	—	69·5
	93·2	3·9	6·2	< 1·2	72·0
	96·3	5·14	7·2	—	71·5
	88·2	4·37	2·4	—	74·5
Average of 4 specimens	93·0‡	4·2‡	5·3‡	< 1·2‡	71·9§

The *p*H of freshly drawn blood is 7·3‖.

Methods: * EEL flame photometer; presence of other ions not allowed for.
† Ethylenediamine tetraacetic acid titration.
‡ Unicam flame spectrophotometer *S.P.*900.
§ Electrometric titration.
‖ Beckman drop electrode.

Table 2. Composition of Peripatus Ringer's Solution

	Stock solutions M	Stock solutions g/l.	ml.	Final m.equiv./l.
NaCl	0·54	31·6	198·0	106·9
KCl	0·54	40·2	9 25	5·0
$CaCl_2 \cdot 6H_2O$	0·36	78·2	9·20	6·6
$MgCl_2 \cdot 6H_2O$	0·36	36·6	2·0	1·4
$NaHCO_3$		2·0	2·5	0·6
NaH_2PO_4 anh.		0·1	5·0	0·1

Distilled water added to make up to 1,000 ml. Final *p*H is 7·3.
Glucose: 0·4 g added to 100 ml. before use.

The analyses were based on whole blood, but the ions contained in blood cells can contribute little to the total since haemocytometer counts for six animals indicate only an average of about 5,000 cells/mm³. Two counts by Tuzet and Manier[11] give an average of 2,000 cells/mm³. As the blood cell volume must be less than 0·5 per cent of the blood volume, even the potassium contribution of the cells would be at most only 5 per cent of the whole blood potassium-levels, while that of other ions would be negligible. The blood does not clot.

Dissected preparations of the neuromuscular system remain viable in the physiological saline for at least 12 h at 20° C.

Simultaneous measurements of blood osmotic pressure were not made, but a level very close to 110 mmole/l. sodium chloride, the average of values found by Picken[1] for species of *Peripatopsis*, would be expected if inorganic ions account for the major part of the total concentration.

The animals normally live in moist microclimates and show a preference for high humidities[2]. In dry air they lose water rapidly owing to evaporation from the numerous tracheal openings[3,4]. Those used for the present determinations were kept beforehand under rotting wood on damp cotton-wool, and it will be noted that there is relatively little variation between individuals in the ionic composition. This implies that in favourable conditions the body-fluid concentration is accurately regulated. Certain of the regulatory mechanisms involved are known. Water which might otherwise be lost in the excretion of nitrogenous waste is conserved by the secretion of uric acid into the gut[5]. The nephridia produce hypotonic urine and are probably emptied infrequently[1,5]. In some species water can be taken up from moist surfaces by eversible coxal sacs[6]. Despite these conservatory devices there is likely to be a net loss of water from the body if the animals are exposed to drying conditions. It is interesting to note therefore that the blood concentration is very low in comparison with that of terrestrial arthropods of comparable size belonging to the classes Crustacea, Myriapoda, Arachnida and Insecta[7–10]. It is possible that this low tonicity may be of advantage to an animal occasionally liable to suffer desiccation, since a given water loss will concentrate the body fluids by a smaller absolute amount than if the concentration were higher. Consequently if the volume of any cells is to be maintained constant, the necessary adjustments to the internal osmotic activity and ion-levels will also be of smaller magnitude than otherwise would be the case.

Effects and After-effects on Planarians of Reversals of the Horizontal Magnetic Vector

The freshwater planarian, *Dugesia dorotocephala*, was investigated at Evanston, Illinois, to learn whether it displayed orientational responses to abrupt experimental reversals of the horizontal vector of magnetism comparable with responses recently reported for marine mud-snails, *Nassarius obsoletus*, at Woods Hole, Massachusetts[1]. The study of the planarians extended over the period from April 12 to September 25, 1962, which included nearly 6 synodic months.

Observations were made between 9 and 11 a.m. on 25 days of the first month, 22 days of the second, and 24, 27, 21 and 16 days of the succeeding synodic months, respectively. Each morning two observers independently determined the mean turning rate over a 1-in. course for 15 paths of initially northbound planarians under each of eight experimental conditions in a fixed three-light field in a manner previously described[2,3]. One of the observers alternated the assaying of worm paths in the Earth's field (controls) with worm paths in each of four experimentally reversed fields (0·05, 0·2, 1·0 and 4·0 gauss) presented in shuffled order. The other observer performed the same kind of experiment except for using different field strengths (0·1, 0·5, 2·0 and 6·0 gauss). Each observer worked alternately with the 0·05- to 4·0-gauss and the 0·1- to 6·0-gauss series. The observers were uninformed of the order of presentation of the reversed magnetic strengths and of whether their alternating series commenced with a control or with an experimentally reversed field. Five worms remained in the small orientation vessel and were

repeatedly used to obtain each complete series of 120 paths, and then these worms were discarded. The entire investigation involved assay of 32,400 paths using 1,350 different worms.

One additional variable was present in the experiment. Whether on any given day the experiment was performed in an equi-potential right–left electrostatic field, a consequence of the presence of interconnected, large, vertical aluminium plates to right and left[4], or simply was performed in the unmodified right–left electrostatic gradient existing at the time, was determined by lot.

Fig. 1 shows the difference between mean planarian path while in each of the eight reversed field strengths and the average of all the controls in the same series. The series which were run in the equi-potential right–left field (solid circles) and those run in the unmodified electrostatic field (open circles) are shown separately, together with standard errors of means ($N > 100$). The similarity of these two emphasizes the general reproducibility of the results during this period and indicates that at least over the greater portion of the experimental range no significant influence of the right–left electrostatic gradient on the response was observable. However, at the two ends of the range, the presence of the plates suggestively sharpened a mean response to the 0·05-gauss field and, on the contrary, essentially abolished a mean response to the 6-gauss one.

The dotted curve in Fig. 1 illustrates, for comparison, the corresponding relationship between strengths of reversed fields, within the same range, reported[1] for southbound mud-snails which were observed at Woods Hole, Massachusetts, during July and August of the same year by other observers. Neither group of observers was informed of the results being obtained by the other one. The form of the relationship, though exhibiting about a 1° displacement, is remarkably similar for the two species. With the 1° displacement it is evident that a maximum in snail response (in this case left-turning) occurred near 0·1 gauss. This is consistent with the published report[5] that the mean turning behaviour of north- and south-directed snails differs significantly one from another. On the other hand, the presence of a minimum in mean turning response of planarians at 0·1 gauss is consistent with the previous report[3] that the mean paths of north- and south-directed planarians are indistinguishable from one another even though both are highly significantly different from those of east- or west-directed worms. The existence of the minimum at 0·1 gauss instead of 0·5 gauss suggests an adaptation of planarians to the strength of the horizontal vector at the specific local

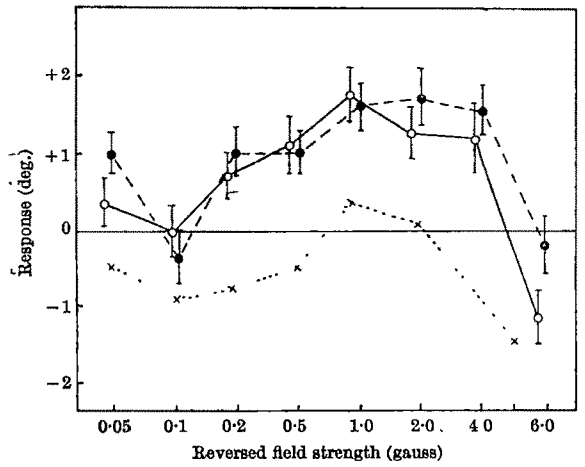

Fig. 1. Response of planarians, expressed as path difference from the controls, to each of a series of strengths of reversed horizontal magnetic vectors while otherwise in either the natural field (open circles) or a right–left equipotential electrostatic field (solid circles), and for mud-snails (× - - - ×) studied elsewhere during the same year (ref. 1). Standard errors of means ($N > 100$) are shown

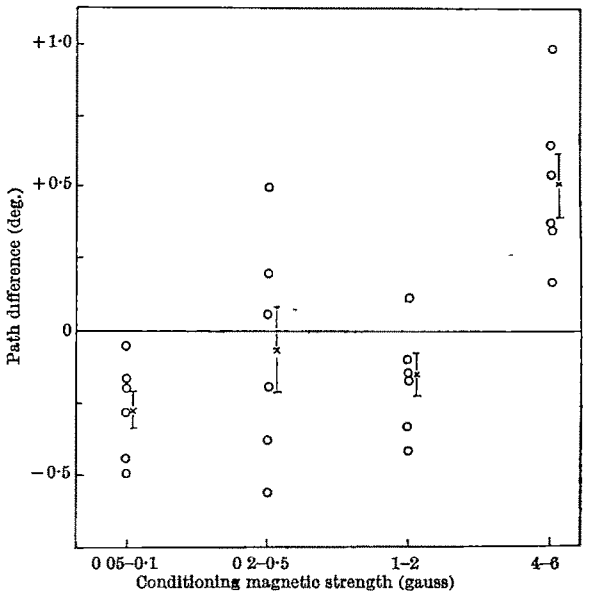

Fig. 2. The differences, for each of 6 synodic months, of the paths of north-directed control planarians from the mean of all control paths for that month, during 5-min periods following termination of 5-min exposures to reversed horizontal magnetic vectors at each of four strength-ranges. Means and their standard errors ($N = 6$) are also shown

geographic latitude in contrast to total field strength, just as had been demonstrated for mud-snails[1].

The data were next examined to learn whether exposures to the reversed horizontal magnetic vectors were followed by any after-effects. The duration of exposure to an experimentally reversed magnetic field averaged about 5 min, the time required to observe fifteen paths, and similarly the assay for any after-effect of an experimentally altered field-strength expressed as altered behaviour of the following controls, extended over about a 5-min period immediately after removal of the experimental field.

The data were reduced to synodic monthly units and the mean path of the controls in the Earth's field for each month was correlated with the strength of the reversed magnetic field that immediately preceded it. Data for controls when first in a series were discarded. The monthly unit was selected in view of the well-established monthly variation in response of both snails and planarians to very weak magnetic fields. Also, such a unit period was long enough to randomize in large measure any influences of other, uncontrolled weather-system-related geophysical variations on the phenomenon under investigation.

In Fig. 2 the mean path of the control worms is plotted for each of the 6 synodic months of data in relation to strength of the immediately preceding reversed experimental magnetic field. Mean path for each of the four control groups is expressed as the path difference from the mean path for all the controls of that month. It is evident that following those field strengths that deviated by no more than a factor of 4 (0·2–2·0 gauss) from the Earth's total field of about 0·5 gauss, the control values did not differ significantly from the mean for all controls. However, following the weakest fields (0·05 and 0·1 gauss) there was an after-effect in the form of a significantly increased counter-clockwise turning. Following the strongest fields (4 and 6 gauss) there was increased clockwise turning. Analysis of variance of the four populations of values yielded $F = 9{\cdot}9$ ($P < 0{\cdot}001$), indicating that the controls following the four strength-ranges of magnetism were, with very high probability, not random samples of values from a homogeneous population.

It is noteworthy that the after-effect shown by the planarians is qualitatively of the same general character as that reported previously for mud-snails[1], namely,

increased clockwise turning following fields stronger than the Earth's and increased counter-clockwise turning following fields weaker. This similarity obtained despite the fact that the snails had been south-directed while the planarians in the present investigation were north-directed.

Inspection of Fig. 1 reveals that the worms turn less far to the right in response to the 4- to 6-gauss fields than to the 1- to 2-gauss ones, and right-turning response to the 0·05- to 0·1-gauss fields averages about the same as to the 4- and 6-gauss ones. Therefore, the highly significant differences in after-effects among these ranges as shown in Fig. 2 cannot be attributed simply to a tendency of the worms to maintain in the subsequent control field the same path in the orientation apparatus that resulted from direct response to the experimentally reversed magnetic fields. Some other explanation must be sought. It is postulated that the phenomenon reflects acclimation or accommodation of the magnetoreceptive mechanism toward the altered strengths. This behaviour is interpreted as further evidence suggesting that the organism is, normally, physiologically adjusted in some manner to the strength of geomagnetism, even to specific vector strengths.

The general similarities of responses of the planarians to those obtained earlier for mud-snails suggest that responsiveness to the horizontal magnetic vector may be a fundamental and widespread biological property.

This work was aided by grants from the National Institutes of Health (*GM*-07405) and the National Science Foundation (*G*-15008), and by a contract with the Office of Naval Research (1228–30).

Distribution of the Genus *Nephrops* (Crustacea Decapoda Macrura) in the Indo-Pacific Region

A survey of the northern part of the South China Sea recently carried out by R.V. *Cape St. Mary*, of the Fisheries Research Station, Hong Kong, has shown that considerable numbers of *Nephrops* spp. (Crustacea Decapoda Macrura) are present in this region. Four species have so far been obtained: *N. thompsoni* Bate, *N. sagamiensis* Paris, and two which are new[1]. The most abundant species is *Nephrops thompsoni* Bate, previously known only from the original specimen obtained by the *Challenger* Expedition and a second specimen from Formosa[2]. One of the new species is almost equally abundant.

The widespread occurrence of these lobsters has been revealed during the systematic trawling survey of the South China Sea being carried out as part of the programme of R.V. *Cape St. Mary*. Further prospecting cruises are being undertaken to determine whether or not *Nephrops* is present in commercially exploitable quantities.

In the northern part of the South China Sea *Nephrops* has been found only on soft muds off the edges of the continental shelf, mainly between 100 and 200 fathoms, although one species was obtained at 450 fathoms. Attempts to catch *Nephrops* on oceanic banks have so far been unsuccessful. In November 1964, R.V. *Cape St. Mary* obtained *N. thompsoni* at 94–98 fathoms off North Borneo. The original record of this species was from the Philippines between Manila and Samboang. The results so far obtained indicate that *N. thompsoni* is probably present all around the continental slopes of the South China Sea.

The European *Nephrops norvegicus* (L.) is now extensively exploited by the north-west European and Mediterranean fisheries, where it has become a luxury product sold under such names as scampi, langoustine and Dublin-Bay prawn. Until recently the tropical species of *Nephrops* has not been exploited, but a commercial fishery based on the New Zealand species, *N. challengeri* Balss, is now being developed[3,4]. *N. norvegicus* is abundant in depths of 25–50 fathoms and its fishery presents no special problems. The Indo-Pacific species occur mainly at depths of more than 100 fathoms where few local vessels are yet able to fish.

No systematic surveys have been undertaken for *Nephrops* in tropical waters, but the recent results obtained in the South China Sea by R.V. *Cape St. Mary* indicate that this genus may be more abundant and widespread than has been supposed. Two new species have recently been found in Australian waters[5,6], and there are numerous scattered records from the Indian Ocean. The purpose of this communication is to draw the attention of fishery research workers in the Indo-Pacific region to the possibility that quantities of *Nephrops* may be present at suitable localities and depths, and that further efforts should be made to investigate their distribution and biology. Any further information concerning the distribution of adult *Nephrops*, or their larvae, in the Indo-Pacific region would be welcomed by me.

ENTOMOLOGY

Ascorbic Acid in the Larval Stages of *Plusia signata* (Lepidoptera : Noctuidae)

Day[1] found that in the larva of *Tineola*, the columnar but not the goblet cells contain vitamin C. Dadd[2] reported that vitamin C is essential in the development of *Schistocera gregaria*. Gilmour[3] found ascorbic acid widely distributed among insects and synthesized by them. An investigation of different larval instars of *Plusia signata* was undertaken to determine the distribution of ascorbic acid in different tissues in these stages.

The histological presence of ascorbic acid was demonstrated by the silver method as modified by Bacchus[4], and its estimation was performed by the indophenolxylene extraction method of Robinson and Stotz[5].

Histological sections showed that the presence of ascorbic acid was greatly marked in different tissues during different instars. First instar larvae which had hatched about 1 h before, and which had not yet started feeding, showed even impregnation throughout the gut epithelium and blood cells. The cells of the spinning glands exhibited very little impregnation, in fact, only localization in the supra-nuclear regions of the cells. Fat bodies and nerve cells also contained small amounts of ascorbic acid. In the second and third instars, the accumulation of ascorbic acid appeared to have increased only in the mid-gut epithelium and blood cells. The cells of the spinning glands in these stages exhibited very slight increase of ascorbic acid, but the impregnated cells now showed an even distribution throughout: the ascorbic acid was not

limited only in the supranuclear zone as in the previous stage. During fourth and fifth instars, the cells of the mid-gut epithelium, cells of hepatic caecae and the epithelial cells of the hind-gut showed heavy impregnation. Cells of fore-gut epithelium and nerve cells did not indicate any increase in the ascorbic concentration. Heavy impregnation of the spinning gland cells was now found mostly towards the lumen surface of the cells. The fat body and blood cell also showed considerable concentrations of ascorbic acid in these latter instars. A comparative investigation of different instars showed that there was a gradual increase in the amount of ascorbic acid in different tissues as the larva grew, except in the case of nerve cells. Estimation of ascorbic acid during different instars based on the extracts of whole larvae also indicated such gradual increase (Table 1).

Table 1

Instars	mg/g
First instar larva	0·08
Second instar larva	0·35
Third instar larva	0 49
Fourth instar larva	0·71
Fifth instar larva	0·82

From both histological examination and extract estimation, it is evident that high concentration of ascorbic acid is found in the larval life. This ascorbic acid does not appear to be purely of dietary origin, as in the first instar larva, which had not started feeding, an appreciable quantity of ascorbic acid was found in the tissues. The gradual increase in the amount of ascorbic acid from first instar to the last suggests that ascorbic acid is required during the process of metamorphosis during the formation of adult organs.

I thank Dr. S. Keshava for his advice and various facilities.

MICROBIOLOGY

Inhibition of Yeast Growth by Streptomycin

For the isolation of a pure culture from yeast cultures heavily contaminated with bacteria, sub-cultures were made into media containing penicillin and streptomycin. With certain yeasts we observed that yeast growth as well as bacterial growth was inhibited. Preliminary observations suggested that the streptomycin was the inhibitory agent. This observation contradicts earlier opinion which considered fungi, including yeasts, to be insensitive to the action of streptomycin[1,2]. Based on this opinion of insensitivity to streptomycin, some media designed for the isolation of pathogenic[3] and saprophytic[4] yeasts include streptomycin, at a concentration of 40 μg/ml., to inhibit bacterial growth.

However, partial inhibition of yeast growth by streptomycin at the high concentration of 100–10,000 μg/ml. (ref. 5), and also partial inhibition of a variant of *Torula utilis* by 13 μg/ml. of streptomycin[6], have been reported. This communication describes experiments which were designed to measure quantitatively the streptomycin-sensitivities of yeast strains from the National Collection of Yeast Cultures which appropriate screening had suggested to be sensitive to this agent.

The streptomycin-sensitivities of the yeast strains were assessed in M.Y.G.P. (ref. 7) except for the osmophilic strains which were assayed in osmophilic medium (malt extract 0·3 per cent, yeast extract 0·3 per cent, sucrose 40 per cent, dextrose 5 per cent, peptone 0·5 per cent). The final *p*H of both types of medium was 6·9–7·0. Streptomycin sulphate was added aseptically to the medium just prior to inoculation. As the nature of the medium has been demonstrated to have a significant effect on the activity of streptomycin towards yeasts[5], a complex medium was deliberately chosen for assay so that inhibition of yeast growth in the assay system would then reflect the probability of inhibition of yeast growth occurring during laboratory isolations. Assays were performed in 10 ml. amounts of medium, and each tube was inoculated with a standard loopful of a 3-day yeast culture ($4·5–11 \times 10^4$ yeast cells per tube). Incubation was at 25° C for 72 h on an automatic shaker (3 cm amplitude, 80 cycles per min). The degree of growth at the end of this period was assessed visually.

Table 1. Sensitivity of Yeasts to Streptomycin

Yeast	N.C.Y.C. No.	Growth in presence of streptomycin sulphate (μg/ml.) 0	10	20	50	100
Candida utilis	193	+	+	+	+	+
Endomycopsis fibuliger	13	+	+	Sl†	–	–
Hansenula anomala (*O*)*	522	+	+	+	+	+
Hansenula subpelliculosa (*O*)	558	+	+	+	+	+
Saccharomyces acidifaciens	464	+	+	+	–	–
Saccharomyces carlsbergensis	511	+	+	+	Sl	–
Saccharomyces carlsbergensis	519	+	+	+	–	–
Saccharomyces carlsbergensis	520	+	+	+	+	–
Saccharomyces cerevisiae	83	+	+	+	+	Sl
Saccharomyces elegans	128	+	+	+	–	–
Saccharomyces ludwigii	364	+	+	+	–	–
Saccharomyces rosei	492	+	+	–	–	–
Saccharomyces rouxii (*O*)	381	+	+	+	+	–
Saccharomyces rouxii (*O*)	581	+	+	+	+	+
Schizosaccharomyces octosporus (*O*)	427	+	+	–	–	–

* (*O*) Denotes osmophilic strain.
†Sl denotes slight growth.

Table 2. Effect of *p*H on Inhibitory Action of Streptomycin towards Yeasts

Yeast	N.C.Y.C. No.	*p*H	Growth in presence of streptomycin sulphate (μg/ml.) 0	10	20	50	100
Saccharomyces elegans	128	4·7–5·0	+	+	+	+	Sl
		5·7–6·0	+	+	+	–	–
Saccharomyces acidifaciens	464	4·7–5·0	+	+	+	–	–
		5 7–6·0	+	+	+	–	–
Saccharomyces rosei	492	4·7–5·0	+	+	Sl	–	–
		5·7–6·0	+	+	Sl	–	–
Saccharomyces carlsbergensis	519	4·7–5 0	+	+	+	+	–
		5·7–6·0	+	+	+	Sl	–

The results summarized in Table 1 appear to be the first demonstration that streptomycin at such low concentrations can completely inhibit the growth of a variety of yeasts during the incubation period. Furthermore, the degrees of sensitivity of the various species tested suggest that the level of streptomycin incorporated into media for isolation of yeasts may inhibit some yeast strains as well as bacteria. Media used for the isolation of yeasts are of lower *p*H than the assay media, but Table 2 reveals that reduction of *p*H to 5·7–6·0 has little effect on the degree of sensitivity of these yeast strains to streptomycin, and even at *p*H 4·7–5·0 some yeast strains could still be inhibited by the concentration of streptomycin in these media.

In the light of these observations, therefore, it would appear unwise to incorporate streptomycin routinely in any medium designed for the isolation of yeasts.

We thank Dr. A. H. Cook for his advice and encouragement.

Sporogen—an 'Inductor' for Bacterial Cell Differentiation

CELLULAR differentiation has proved to be one of the most fascinating subjects for investigations in the field of biology. Since Spemann's[1] discovery of the phenomenon of induction by organizers, numerous investigations have been directed towards the isolation and identification of inductor substances in morphogenesis. Efforts to obtain such genotropic substances and to analyse the mechanisms of their actions have so far been unsuccessful. In my investigations, bacterial sporogenesis has been taken as a model system for studying the biochemical aspects of intracellular differentiation.

My colleagues and I reported earlier[2] that an endogenous factor was present in the early stationary phase of growth of *Bacillus cereus* strain *T*. This factor played an active part in triggering the vegetative cells to the sporulating stage. It has now been fractionated and a biologically active substance isolated by means of the method which we used to detect biological activity in our previous communication[2]. The trivial name of 'sporogen' has been given to the crystalline material.

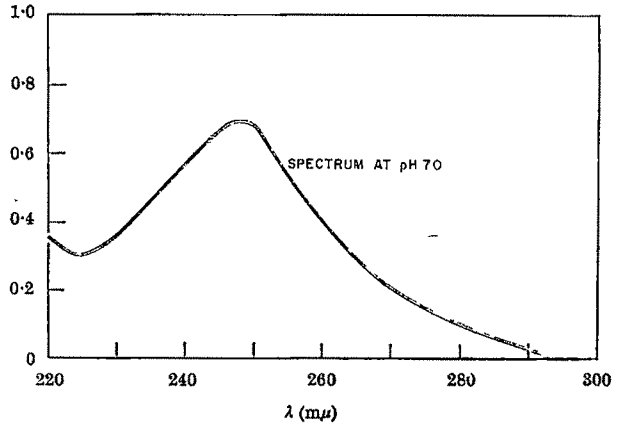

Fig. 1. Ultra-violet absorption spectrum of sporogen

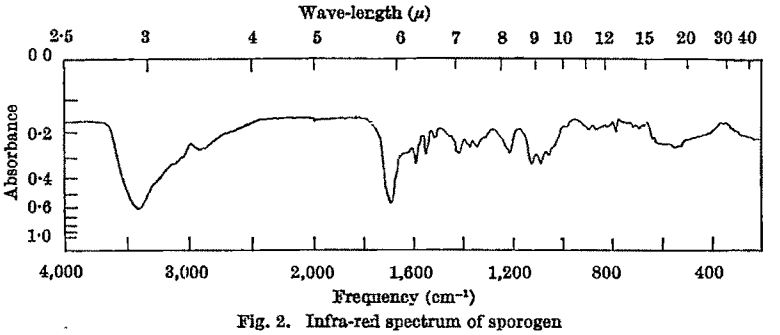

Fig. 2. Infra-red spectrum of sporogen

The procedure for the isolation of sporogen from 5 lb. (wet weight) of *B. cereus* strain *T* cells was as follows. The cells were suspended in 2·5 l. 0·01 M potassium phosphate buffer at *p*H 6·8. The suspension was mixed with an equal volume of glass beads (100μ in diameter obtained from Minnesota Mining and Manufacturing Co.), and the cells disintegrated by passing the mixture through an Eppenbach Colloid mill. The glass beads were removed by decanting off the fluid after allowing the mixture to stand for a while; the cell debris and unbroken cells were obtained by centrifugation. The clear supernatant fluid was adjusted by adding hydrochloric acid so that it had a *p*H of 2·0; at this *p*H a precipitate formed and this was removed by centrifugation. The solution, golden yellow in colour, was adjusted to *p*H 5·5, this time using potassium hydroxide, and left overnight at 4°–5° C. The small amount of precipitate which formed was removed and the solution was evaporated to dryness under reduced pressure; a residue weighing 100 g was obtained. This material was suspended in 5 l. of a mixture of ethanol formic acid and water in the proportion 90 : 5 : 5 and shaken thoroughly at room temperature overnight. The suspension was filtered off and the filtrate once again evaporated to dryness under reduced pressure; 10 g of residue was obtained. This was treated with a minimal volume of 0·2 N acetic acid and fractionated on a column (50 cm × 5 cm) of 'Sephadex' *G*-25 pretreated with 0·2 N acetic acid. The fractions were monitored by measuring the absorption at a wave-length of 249 mμ in a Beckman spectrometer. The active fractions were pooled, and once the solvent had been removed under reduced pressure, the residue was further fractionated on a cellulose column using a mixture of butanol–acetic acid–water (4 : 1 : 1) as the developing solvent. The fractions were analysed by paper chromatography using the same solvent mixture. Biological activity was exhibited by the fraction with an R_F of 0·35. This fraction was collected, the solvent removed by evaporation under reduced pressure and the residue crystallized from aqueous solution (yield 19 mg). The crystalline substance obtained melted between 162° and 165° C and had an elementary composition as follows: C, 42·78 per cent; H, 4·89 per cent; N, 18·63 per cent; O, 33·7 per cent (by difference). It had a characteristic ultra-violet absorption spectrum with an absorption maximum at 249 mμ (Fig. 1). The infra-red spectrum of the compound is presented in Fig. 2.

The chemical nature of the substance is at present under investigation, but little is known about the mechanism of its action. As a working hypothesis, adopting Jacob and Monod's model[3] for induced enzyme synthesis, it may be taken for granted that sporogen derepresses the regulators controlled by the 'sporogenes', thereby releasing the operator gene which in turn switches on the structural genes responsible for the synthesis of macromolecules which is required for the initial steps in sporulation.

I thank Dr. H. Orin Halvorson for his advice, and Mr. Francis Engle for his assistance. I also thank Dr. J. G. Garver of the University of Wisconsin for making available his facilities for growing large batches of organisms.

These investigations were supported by grants from the Office of the Naval Research and U.S. Public Health Service.

GENETICS

Synchrony of Chromosome Duplication

IN some recent publications statements have been made on the marked asynchrony of homologous pairs of autosomes with respect to duplication of the chromosomes—as studied with tritiated thymidine[1–3]. In an earlier publication, in which quantitative analysis of grain counts on chromosomes has been performed, we have reported that no evidence for a marked asynchrony was found[4].

In view of these apparently contradictory reports, the question was re-examined. The results, which are described here, indicate that there is no detectable

difference between the homologues of the chromosomes investigated. It is possible to pick cells in which a truly striking difference exists between homologues of a pair, but when the painful analysis of grain counts over a significant number of cells is performed, these differences appear no more than the extreme ends of a rather wide distribution. It is not legitimate, therefore, to deduce asynchrony unless supported by statistical evidence.

The material examined included blood cultures from a normal female (case 1), a normal male (case 2) and a female with a large iso-X chromosome (case 3); also skin cultures from a normal female (case 4) and from an XXY male (case 5). The cultures were labelled with tritiated thymidine at the end of the S period so that the cells to be analysed spent only about 30–40 min in the S period. The culture, labelling and autoradiography methods were described previously[2].

Each chromosome in group I (Nos. 1, 2 and 3) was grain counted. The total number of grains over all chromosomes was also counted in each cell, and separate counting was undertaken on the 'hot' X chromosomes in cases 1, 3, 4 and 5 (ref. 5). The total number of cells analysed was 226, and the total number of grains counted was more than 84,000; the total over the group I chromosomes was more than 16,000.

In the analysis of our results we will use the following notation:

a, b, the grains over two homologues in a cell
n, the total grains in the cell excluding the 'hot' X
T, the total number of cells
Σ, a summation made over the T cells
$H = \Sigma(a+b)$, the total grains over the two homologues in the T cells
$N = \Sigma n$, the total grains in the T cells excluding 'hot' X's
$M = H/N$, the mean proportion of grains over the two homologues
p, $(1-p)$, the expected proportion of grains over each homologue
w, the statistical weight given to a cell

Although not distinguishable morphologically, the two homologues are different in so far as each was originally derived from a different parent, but they do not necessarily have different labelling patterns. If we call the two homologues A and B, then, due to the considerable statistical variation, we cannot assign the observed grain counts a and b in any individual cell uniquely to A or B, unless a and b are consistently very different. This is not the case except for the pair of X chromosomes. Differences in labelling intensity may be separated from the statistical noise, but it is misleading to attempt this by assigning the greater of a and b to one homologue and the smaller to the other. This could lead to misclassification in up to half the cases, and the average difference would be difficult to interpret. A better approach is to average the square of the difference $(a-b)^2$, since an analysis of variance can then be made.

We denote p and $1-p$ the expected proportion of grains over the two homologues; p may have any value between 0 and 1; $p = 0{\cdot}5$ corresponding to equal labelling. For the moment we will assume that all the chromosomes in our set of cells have a consistent labelling pattern and that all the observed differences are due to random statistical variations. Some cells have, however, been exposed to the label for a longer period and so have more grains; we shall take n the total number of grains as a measure of exposure and assume these grains to be distributed on average in the same proportions over the chromosomes, independent of labelling intensity.

With these assumptions, the variances of $(a + b)$ and $(a - b)$ about their respective mean values will be the same. In calculating these variances it is necessary to weight the observations. We have used the weights appropriate to a binomial distribution, each cell being given a weight w, inversely proportional to its grain count; that is, the inverse of the expected variance of $(a + b)$:

$$w = \frac{N}{N-H} \cdot \frac{N}{H} \cdot \frac{1}{n}$$

Now the expected value of $(a + b)$ is Hn/N and that of $(a - b)$ is $(2p-1)Hn/N$. We denote by Y_s and Y_d the weighted sums of squares of the differences of $(a + b)$ and $(a - b)$ from their expected values. Therefore:

$$Y_s = \Sigma w\,(a + b - Hn/N)^2$$

$$Y_d = \Sigma w\,(a - b - (2p - 1)\,Hn/N)^2$$

Expanding out of these expressions and using the identities for H and N, we obtain:

$$Y_s = \frac{N}{N-H}\left(\frac{N}{H}\,\Sigma\,(a + b)^2/n - H\right)$$

$$Y_d = \frac{N}{N-H}\left(\frac{N}{H}\,\Sigma\,(a - b)^2/n - (2p-1)^2 H\right)$$

The assumption made here requires the sums of squares Y_s and Y_d to be estimates of the same variance and, equating these, $(2p-1)^2$ and p can be calculated.

Table 1. Details of the Grain Count Analysis of the Homologous Autosomes of Group I

For explanation of the symbols, see list in text

Culture and chromosome		T	N	H	$\Sigma(a+b)^2/n$	$\Sigma(a-b)^2/n$	$(2p-1)^2$

4	1	66	40,084	2,620	186 0968	12 6237	−0 013 ± 0 022
XX	2	65	39,520	2,116	121·2073	4·5564	−0 030 ± 0 018
	3	61	37,775	1,648	78 9804	3 3870	−0·064 ± 0·028
5	1	72	23,722	1,811	152 1511	13 0099	−0·006 ± 0·024
XXY	2	72	23,722	1,913	169 5604	8·0801	−0·047 ± 0·024
	3	72	23,722	1,393	92·5665	6 0463	−0 058 ± 0·031

Table 1 shows the results for the chromosomes 1, 2 and 3 and from five different cultures. It will be seen that except for two of the fifteen cases examined, the estimate of $(2p-1)^2$ is negative. The squared quantity $(2p-1)^2$ must essentially be positive, and the findings in Table 1 therefore indicate that the basic assumption that Y_s and Y_d are equal is not justified. This shows that the variance of the differences $(a-b)$ is less than the variance of the sums $(a+b)$ from its mean.

This unexpected finding indicates that we have no precise way of estimating p. However, it must be remembered that any value of p other than 1/2 involves a smaller variance for the differences between the homologues within the cells than between cells.

The considerable biological variation implies that some large differences in labelling intensity will be expected to be seen and therefore these must not be given undue significance.

Thus the analysis of our data gives not only no evidence for a difference in the number of grains over the pairs of homologues of the chromosomes in group I, but, in fact, shows that the pairs of homologues have on average a smaller difference than would be expected from the observed variance from cell to cell in this narrow 'end of S' cohort of cells.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 31

CIBA FOUNDATION FOR THE PROMOTION OF INTERNATIONAL CO-OPERATION IN MEDICAL AND CLINICAL RESEARCH (at The Royal Institute of British Architects, 66 Portland Place, London, W.1), at 5 p.m.—Prof. C. P. Leblond, F.R.S. (McGill University): "Role of the Golgi Complex in Secretion" (18th (Annual) Ciba Foundation Lecture).

UNIVERSITY OF LONDON (at the London School of Economics, Houghton Street, London, W.C.2), at 5 p.m.—Prof. R. J. Harrison-Church: "Some Geographical Aspects of West African Development" (Inaugural Lecture)*.

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Colloquium on "The Problems of Radiation Pressure and Associated Mechanical Forces".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. F. Hoskins: "The Definition and Properties of the Delta Function".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. M. W. Thring: "The Status and Training of Engineers and Technologists". (Last of three Cantor Lectures on "The Place of the Technologist in Modern Society".)

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. J. Kohn: "The Use of Balsa Wood in Association with Reinforced Plastics".

Tuesday, February 1

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. H. Humphrey: "Cell Damage by Complement" (Sixth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation)*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Prof. P. L. Shinnie: "The Place of Archaeology in African Studies".*

PLASTICS INSTITUTE, LONDON SECTION (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Dr. E. C. A. Horner: "Olefin Copolymers".

Wednesday, February 2

COLOUR GROUP (GREAT BRITAIN) (at Strand Electric and Engineering Co., Ltd., 29 King Street, London, W.C.2), at 3 p.m.—Prof. W. D. Wright: "Colour Tolerances—Yesterday and Today"; Dr. Vickerstaff: "Advances in Colour Recipe Prediction"; Mr. J. G. Holmes: "Temperature Variables in Coloured Light Signals"; Dr. W. S. Stiles, F.R.S.: "Significant Advances in the Field of Colour Vision".

ROYAL MICROSCOPICAL SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Sir Alister Hardy, F.R.S.: "The Development of the Plankton Recorder Method".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Dr. M. A. Champney: "The Electron Beam in Electronics Research and Production".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. R. O. Redman, F.R.S.: "The Surface of the Moon" (Peter Le Neve Foster Lecture).

SOCIETY FOR ANALYTICAL CHEMISTRY (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Meeting on "Determination of Purity in High-purity Organic Materials".

Thursday, February 3

ROYAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 2.30 p.m.—Discussion Meeting on "Structure and Function of Lysozyme", organized by Dr. M. F. Perutz, F.R.S.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. R. Rodnight: "Phosphoprotein Metabolism in the Brain". (Seventh of fifteen lectures on "The Scientific Basis of Medicine", organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (at the School of Pharmacy, Brunswick Square, London, W.C.1), at 5.30 p.m.—Mr. H. E. C. Powers: "Crystallization: a Study in Molecular Architecture". (Further lecture on February 4.)*

CHEMICAL SOCIETY (in the Chemistry Lecture Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Dr. C. B. Colburn: "The Difluoramino Free Radical and Its Derivatives" (Centenary Lecture)

INSTITUTE OF REFRIGERATION (at the National Colleg… lating, Refrigeration and Fan Engineering, South… S.E.1), at 6 p.m.—Mr. P. G. Valentine: "… Store Construction".

Frid…

UNIVERSITY OF L… Du Cane Road…

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. W. S. Metcalf: "Radio Astronomy".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. E. A. Mason: "The Chemical Industry of Japan".

INSTITUT FRANÇAIS DU ROYAUME-UNI (at Queensberry Place, London, S.W.7), at 8.15 p.m.—French Scientific Films.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Dr. Peter Beighton: "Easter Island People".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (preferably with a special interest in the biological sciences) IN HISTORY AND PHILOSOPHY OF SCIENCE—The Secretary, The Queen's University, Belfast, Northern Ireland (February 4).

ASSISTANT LECTURER IN BIOCHEMISTRY IN ST. SALVATOR'S COLLEGE—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (February 5).

LECTURER and an ASSISTANT LECTURER (with special interest in either physical geography and biogeography or in regional studies) IN GEOGRAPHY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (February 7).

LECTURERS or ASSISTANTS IN PHILOSOPHY—The Secretary of the University Court, The University, Glasgow (February 7).

LECTURER (preferably with a special interest in the development of computer software) IN THE COMPUTER UNIT—The Registrar (Room 39, O.R.B.), The University, Reading (February 8)

GRADUATE (with a degree in chemistry, biochemistry or an allied biological subject and a wide general interest in biology) TO ASSIST IN CANCER RESEARCH—The Secretary, King's College Hospital Medical School, Denmark Hill, London, S.E.5 (February 12).

LECTURER and an ASSISTANT LECTURER IN THE DEPARTMENT OF BIOLOGICAL CHEMISTRY—The Secretary, The University, Aberdeen (February 12).

LECTURER or ASSISTANT LECTURER (with interests in soil mechanics) IN ENGINEERING—The Registrar, The University, Manchester, 13, quoting Ref. 8/66 (February 12).

LECTURER IN THE BIOCHEMISTRY DEPARTMENT—The Secretary, Royal Free Hospital School of Medicine (University of London), Hunter Street, London, W.C.1 (February 14).

LECTURER or ASSISTANT LECTURER IN ORGANIC CHEMISTRY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 14).

RESEARCH ASSISTANT (graduate in chemistry or the biological sciences) IN THE DEPARTMENT OF BOTANY to work with Dr. A. J. Peel on transport physiology in phloem tissue using the aphid technique—The Registrar, The University, Hull (February 14).

SECOND CHAIR OF GEOGRAPHY—The Registrar, University College of Swansea, Singleton Park, Swansea (February 14)

ASSISTANT LECTURER IN THE PHYSIOLOGY DEPARTMENT—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (February 15).

CHAIR OF PURE MATHEMATICS—The Registrar, University College of South Wales and Monmouthshire, Cardiff (February 15).

UNIVERSITY DEMONSTRATOR (with an honours degree in an appropriate pure science (for example, biochemistry or physiology) or agricultural science, and preferably teaching and/or research experience) IN ANIMAL NUTRITION—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (February 15).

ASSISTANT LECTURER IN ARCHAEOLOGY—The Registrar, University College of North Wales, Bangor, North Wales (February 16).

EXPERIMENTAL OFFICER IN THE DEPARTMENT OF CHEMISTRY IN THE FACULTY OF SCIENCE to work on an electron spin resonance instrument shortly to be installed in the Department and concerned with the study of inorganic complexes—The Registrar, The University, Manchester, 13, quoting Ref. 9/66 (February 16).

LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, The University, Leicester (February 16).

LECTURER/ASSISTANT LECTURER IN PHYSICAL CHEMISTRY; a LECTURER/ASSISTANT LECTURER IN APPLIED MATHEMATICS; and a RESEARCH OFFICER to assist in the operation of programmes for the College IBM 1620 tape/disc/card system—The Registrar, University College of Wales, Aberystwyth (February 17).

LECTURER or ASSISTANT LECTURER (preferably with research experience, interests, or qualifications in any of the following fields: parasitology, ecology, or small mammal ecology and systematics) IN THE DEPARTMENT OF ZOOLOGY, Ahmadu Bello University, Northern Nigeria—The Inter-University Council, … Bedford Place, London, W.C.1 (February 17)

… SCHOOL OF ENVIRONMENTAL SCIENCES—The Registrar, …ham Hall, Norwich, NOR 88C (February 19).

… IN THE DEPARTMENT OF GENETICS—The … (February 19).

…ith a degree in chemistry) IN THE …ch will include laboratory manage… …y relieving the Professors of much …ity of St. Andrews, Queen's

CHAIR OF BIOCHEMISTRY at the University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (February 28)

CHAIR OF EDUCATION—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (February 28).

IMPERIAL CHEMICAL INDUSTRIES FELLOWS (below the age of 30, with a Ph.D. degree or equivalent research experience) FOR RESEARCH IN VARIOUS BRANCHES OF CHEMISTRY, PHYSICS, BIOLOGICAL SCIENCES, APPLIED MATHEMATICS, ENGINEERING AND TECHNOLOGY AND ALLIED SUBJECTS—The Registrar, Bradford Institute of Technology, Bradford (February 28).

PROFESSOR (with experience in the petroleum industry) OF PETROLEUM GEOLOGY IN THE DEPARTMENT OF GEOLOGY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (February 28).

SECOND CHAIR OF EDUCATION—The Registrar, The University, Hull (February 28).

GRADUATE RESEARCH ASSISTANTS (qualified to register in programmes leading to the M.Sc. and Ph.D. degrees) IN THE DEPARTMENT OF DAIRY AND FOOD SCIENCE—Prof. L. F. L. Clegg, Head, Department of Dairy and Food Science, University of Alberta, Edmonton, Alberta, Canada.

LECTURER or ASSISTANT LECTURER (or exceptionally SENIOR LECTURER) IN MATHEMATICS—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex.

LECTURER or ASSISTANT LECTURER (with special training in entomology, and preferably a particular interest in ecology, or in genetics) IN BIOLOGY at the University of Malawi—The Inter-University Council, 33 Bedford Place, London, W.C.1.

LECTURER or ASSISTANT PROFESSOR IN THE DEPARTMENT OF PHILOSOPHY—The Dean, Faculty of Arts and Science, University of Manitoba, Winnipeg 19, Manitoba, Canada.

MICROBIOLOGIST (young graduate) to take part in a three-year research project on bacterial spore formation—The Secretary, Biochemistry Department, Imperial College, London, S.W.7.

PHYSICIST (with a Ph.D. in physics or qualifications and scientific research experience which taken together are equivalent thereto) at the Australian Atomic Energy Commission's Research Establishment, Lucas Heights, Near Sydney, to work in a small group undertaking research and development in the field of nuclear radiation interactions and detection—Mr. S. Gray, Atomic Energy Adviser, Australia House, Strand, London, W.C.2.

POSTDOCTORAL FELLOW (preferably with some experience in X-ray crystallography) IN THE DEPARTMENT OF CHEMISTRY, to collaborate with Dr. B. Stevens in a study of the photochemistry and radiation chemistry of crystalline aromatic compounds—The Registrar, The University, Sheffield.

SENIOR LABORATORY TECHNICIAN IN THE DEPARTMENT OF BOTANY AND ZOOLOGY to take charge of day-to-day running of botany and zoology degree course laboratories—Head, Department of Botany and Zoology, Sir John Cass College, Jewry Street, London, E.C.3.

ZOOLOGISTS (M.Sc. or Ph.D. with research experience, and preferably some knowledge of histology and histochemistry) to participate in experimental multidisciplinary programmes of basic research in the field of food additive toxicology—The Director, British Industrial Biological Research Association, Woodmansterne Road, Carshalton, Surrey.

Pye precision in gas chromatography

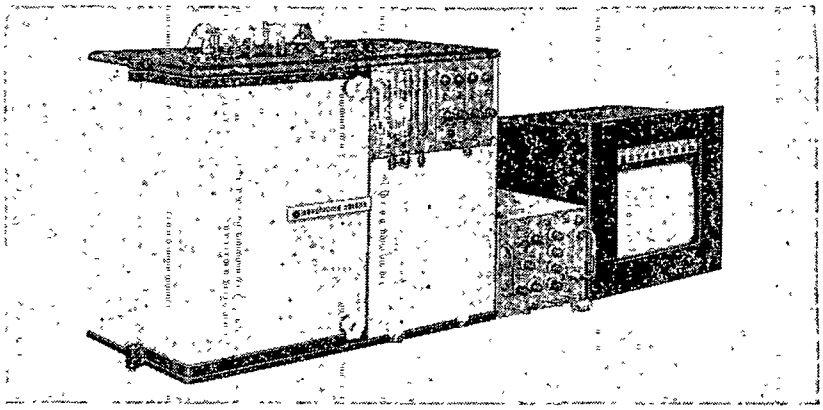
Oven accommodates interchangeable head units incorporating different detector and column configurations and is designed for isothermal or programmed temperature control.

Oven head unit with dual flame detectors, columns and injection ports.

NEW PYE SERIES 104 CHROMATOGRAPHS SPEED ROUTINE ANALYSES

Analysts are changing to the new low-cost Series 104 Chromatograph because its greater speed and convenience save money. They have acknowledged the functional design, the simplified operating features, the comprehensive specification and the overall economy of the system. They are now experiencing its complete reliability under continuous operating conditions.

Four versions of Series 104 are available which cover everyday analytical applications, including steroids, fatty acids, wide boiling range mixtures and high boilers.



The Pye Series 104 Chromatograph gives *faster analysis* with warm-up rates of up to 48°C per minute and operating temperatures as high as 500°C, *easier analysis* due to excellent oven accessibility and design of controls, and *cheaper analysis* with lowest possible outlay and maintenance costs.

Moreover, the Pye Series 104 is designed for continuous development and updating as new techniques emerge.

Please send for the new 20 page illustrated brochure which provides all the technical facts and figures including oven performance data.

PYE PANCHROMATOGRAPHS AID RESEARCH

Leading research establishments in many parts of the world depend upon the versatility of the Pye Panchromatograph to satisfy their most stringent requirements including investigations into the technique and the teaching of gas chromatography. This analytical system can accommodate different detector combinations and column arrangements in two independent ovens, and it features a patented column effluent splitting device which permits further analysis of the column outputs. Numerous optional features including temperature programming, pyrolysis, preparative scale and radiochromatography are available. The Pye Panchromatograph is the first choice for an all-purpose instrument for research.

The Panchromatograph will accommodate six different types of detector, singly or in pairs.

THE PLIGHT OF BASIC CHEMISTRY RESEARCH

IN the fascinating and well-documented Westheimer Report, *Chemistry: Opportunities and Needs**, American scientists have received some answers to the 64,000-dollar question, "What is the role of basic chemistry research in the United States and is sufficient financial support available to enable this role to be adequately filled?"

The 222-page document is the result of the rapid and remarkable team-work of thirteen leading professors of chemistry and two senior industrial chemical research directors, under the chairmanship of Frank H. Westheimer, of Harvard. This body, termed the Committee for the Survey of Chemistry, was set up in 1964 by the National Academy of Sciences–National Research Council in order to investigate the widespread belief among scientists that American basic research in chemistry has been handicapped by a grave shortage of funds. Financial support for the survey to the extent of 50,000 dollars was provided by the National Science Foundation and the American Chemical Society.

In a comparatively short period of time (two years) the Committee has gone to a great deal of trouble to find out all it can about basic chemistry in the United States and other leading countries. It considered it to be necessary to define from the start what 'chemistry' means; 40 pages of the Report have been devoted to a delightful essay entitled "Basic Research in Chemistry", which deals with current trends in the chemistry of everyday life and its impact on other scientific disciplines. In this the Committee has high-lighted a number of outstanding discoveries, quoting authorship, which naturally brings American scientists to the fore. Among the topics covered are structure, physical properties and characterization, syntheses (particularly of molecules of biological importance), chemical dynamics, reactions in solution, and in biological systems, liquids, solids and surfaces, theoretical chemistry and spectra, and nuclear chemistry. These unquestionably have a great impact on the whole world of science. Some hints are given as to how basic concepts are applied to industrial processes. Quoting from the past, it is cited "that the structural theory of organic chemistry which was originated in Ghent in 1858–65 led promptly to the great German dye industry . . . subsequently the theory has provided the framework for the development of the plastics and pharmaceutical industries". Some will say that this is a far-fetched statement, but the meaning is clear. More precisely it is stated that "the electrochemical industry from chlorine to aluminium is based on the theory of ionization".

We have the statement that "another way of confirming the relationship between basic research and the practical world is by examination of publications from industrial laboratories that announce useful inventions". From a study of these in which citations to previous publications are given in footnotes, it is shown that an overwhelming percentage of the citations refer to publications in fundamental journals and a majority to university research. Figures are provided to show that this particularly applies to the great list of pharmaceuticals and industrial chemicals produced since the end of the Second World War. Basic chemistry and current chemical research point the way to the future. Some complacency is perhaps sensed in the statement that "the data also support the contention that the Chemical Industry, especially in the United States, is remarkable and perhaps unique for the speed and vigour with which it incorporates advances in fundamental science into the body of useful knowledge".

The Report compares chemistry in the United States with chemistry elsewhere. Here the number of papers and patents dealt with by *Chemical Abstracts* provides a means of estimating the share contributed by each nation to the total publications for any particular year, and "as recently as 1960 these indicate clearly that the United States led the World". The Committee could obviously not give a direct assessment of the impact or significance of these papers, but tables have been drawn up showing the citation in publications from other countries to American literature: again the United States leads.

The 'brain drain' (so aptly described as "the free flow of young scientists") has also been used by the Committee as a measure of the quality of basic research. Figures given show that no less than 1,000 European post-doctorals (one for every ten graduate chemistry students) are working in basic chemistry in the United States. (European tax-payers might do well to ponder what this loss, albeit partly temporary, of expensively trained alert minds will mean to their future economy.) The number of Nobel prizewinners in Chemistry is also used as a yardstick, and the United States comes out well, being second only to the British (six winners) with four (R. B. Woodward has since become the fifth) out of the fourteen between 1954 and 1964. Further evidence of American leadership in chemistry is shown by the almost complete dominance of *Chemical Abstracts* in summarizing the chemical literature throughout the world.

Some very striking figures give a good idea of the weight and importance of the chemical industry in the United States. Allowing for lack of precise information from the U.S.S.R., it is claimed that the dollar volume of the chemical industry in the United States is 40 per cent of the world total. In 1962 it produced 32,800 million dollars total value of products compared with 22,900 million dollars produced in Western Europe, and this it did with about half the labour force of Western Europe. Exports in that year were 1,900 million dollars and imports 500 million dollars. European exports were 2,500 million dollars and imports 2,600 million dollars. The growth rate of the European chemical industry is 10 per cent, whereas that in the United States is 6 per cent. All these

* National Academy of Sciences–National Research Council. *Chemistry: Opportunities and Needs* (A Report on Basic Research in U.S. Chemistry by the Committee for the Survey of Chemistry, National Academy of Sciences–National Research Council) Pp. 222 (Publication 1292). (Washington, D.C.: National Academy of Sciences–National Research Council, 1965) 5 dollars.

figures lead to the statement in the Report that the "U.S. Chemical Industry is the largest in the World, and is successful in competing in World Markets".

Attention is directed to the considerable renaissance in chemistry and biochemistry due largely to the development of modern electronic instruments such as mass spectrometers, infra-red, ultra-violet, nuclear magnetic resonance and electron-spin spectrometers, vapour phase chromatographs and other instruments. A survey of several thousand articles in various journals shows that the use of such instruments has increased six-fold in the United States and that this has drastically changed the pattern of chemical research. Attention is directed to the remarkable developments in X-ray crystallography. It is claimed that six of the major instruments are used to about the same extent in the United States, Great Britain, Germany and Japan—all these countries being well ahead of the U.S.S.R. in their use. Great Britain has the lead in X-ray diffraction studies, while the United States is well ahead in the use of computers.

A critical survey is made of the important question of the financing of basic chemical research in the United States and other leading countries. Since the Second World War, the overall pattern of support in the United States has changed from private to Federal funds. In 1964 about 100 million dollars of the Federal support for research went to chemistry. In 1963 the American chemical industry spent 1,250 million dollars on research and development and 140 million dollars on basic research. The total expenditure for 1,300 Ph.D.s in 1964 was between 85 and 95 million dollars, that is, about 70,000 dollars for each Ph.D. awarded, with another 5,000 dollars added for the depreciation of laboratories. Of this, the Government contributes 30,000 dollars per Ph.D. These are surprisingly high figures and are indicative of the high measure of instrumentation.

It is claimed, using figures for chemical research in 1959–60 from *Returns from Universities and University Colleges in Receipt of Treasury Grants*, that the percentage of total research expenditure in Great Britain was 13·6 per cent, whereas chemical research in the United States receives only 5·6 per cent of the Federal total expenditure on research. The Report states: "Chemistry in Great Britain has responded well to the nourishment it has received. The quality of the research in Chemistry is high—note the high proportion of British Scientists among the Nobel laureates".

All the facts and figures collected in the Report, whether strictly accurate or not, are the best available and serve to show that basic chemical research in the United States is insufficiently supported and is greatly in need of increased resources. It is considered that even an immediate increase of 16 per cent in financial support would be inadequate for proper support of chemistry in the United States. The present 'back-log' in needs for chemical instrumentation in universities has been estimated to be 20–30 million dollars and only an additional expenditure of 7 million dollars per annum over and above the normal for the next 3–5 years would allow the universities to catch up. Great emphasis is placed on the growing need of chemists for the use of computers: it is claimed that 15 million dollars would be needed to cover the cost of these. Chemistry also needs funds for specialist projects, particularly those involving techniques of X-ray crystallography. The Committee considers that support for basic chemistry research at universities will need to increase from the 61 million dollars in 1965 to 121 million dollars in 1968. (Some idea of the present rate of increase of financial support can be gained from the fact that in 1964 over-all support was 50 million dollars.)

Some interesting specific recommendations are made. Thus, support of basic chemical research should be extended at the annual rate of 20 per cent for 3 years and 15 per cent for several years further. It is suggested that 5 million dollars should be set aside to meet applications from 'young chemists'. Universities are recommended to modernize their chemistry departments and laboratories. The curricula should be examined and improved and the 'post-doctoral system' should be investigated. It is suggested that the chemical industry could well increase its support of university education and research.

In support of its recommendations, the Committee comments that increments of the order recommended are not "blue sky fancies" or even bold planning; the point is made that the amount at present allocated by the Federal Government to explicit support of basic chemical research in universities in 1 year is equivalent to 5 weeks of Federal expenditure for basic research in the Earth sciences and to only 4 days of the National Aeronautics and Space Administration budget.

We wish our American chemistry friends all success in their aims and ambitions, but we must also look to our own position. In total amount, the figures given in the Report will be quite staggering to British chemists, and Britain's scientific advisers to the Ministry of Education and Science should sit up and take notice. Has anyone in Britain really tried to find up-to-date information regarding the cost of basic chemistry (or indeed any other science) in the universities of Great Britain? At the present time the University Grants Committee is investigating the comparative costs of undergraduate teaching and research. Its method of doing this is not the most efficient and is upsetting a great number of university staff. University research is so closely linked with teaching that it is quite pointless to separate the two.

What Britain needs is a rapid and concise 'Westheimer Report' on the financing of all basic scientific research in the universities of Britain. She needs this to show the Treasury how badly financed basic research is and how very much she needs to keep up with the Americans and the rest of the world in this area. For chemistry, between them, the University Grants Committee and the Department of Scientific and Industrial Research in the past have done their best with the funds at their disposal. In many parts of Britain many fine new chemistry laboratories have been built and when built have been lavishly equipped with the most modern instruments. In other places, however, some considerable chemistry 'slums' still exist; because it is impossible to obtain an equipment grant except for a new building, a great number of nearly obsolete instruments are still in use.

The former Department of Scientific and Industrial Research did its best to fill in some of the gaps, and no doubt the Science Research Council with more than £0·75 million per annum available for basic chemistry research projects will continue to do what it can; however, it is essential that it makes a special point of encouraging some of the younger chemists. There is great need for the University Grants Committee and the Science Research Council to work in close harmony on the financing of basic research: there are some signs that closer co-ordination is already in operation.

Support from the British chemical industry for university research, although very welcome, is relatively small and confined to fellowships or scholarships and the

occasional small piece of apparatus on loan. Possibly the best way that the industry could help would be to place contracts with university departments for some of its more speculative long-range research projects.

Basic research in chemistry and other sciences must be kept in the healthy state it enjoys at present. If Britain is to maintain her present advanced position a considerable increase in financial support must be forthcoming from the Government and industry.

TOWARDS A RATIONAL FUEL POLICY

A MAJOR feature of the meeting of the British Association for the Advancement of Science at Cambridge was the plenary symposium on "World Fuel and Power Resources and Needs" on September 6, 1965. The six papers contributed were published almost simultaneously, with an introduction by Sir Cyril Hinshelwood, in a special issue of *The Advancement of Science*. They provide an appropriate background against which to consider the White Paper on *Fuel Policy** which came from the Ministry of Power in October. This is especially so as, in the final contribution to the symposium, Prof. A. R. J. P. Ubbelohde called in question the whole basis of British policy for energy even more unequivocally than did Political and Economic Planning in its recent Broadsheet, *Questions of Fuel Policy* (see *Nature*, 208, 24; 1965). The symposium itself was indeed intended to stimulate answers to such questions as the magnitude of world needs for fuel and power and the potential contributions and limitations of coal and oil and natural gas, as well as of nuclear energy and hydro-electric power. It sought also to assess the significance of new inventions such as the fuel cell and magneto-hydrodynamics, together with the implications of the answers to the foregoing questions for the less-developed countries.

It was appropriate that the symposium should have been opened by a paper on the world's needs from Sir Harold Hartley, who from 1950 until 1956 was president of the World Power Conference and who had devoted his presidential address to the British Association in 1950 to "Man's Use of Energy" (*Nature*, 166, 368, 636; 1950). Sir Harold concluded his address with a quotation from the final words of his presidential address, from which he saw no reason now to dissent: "On man's wise use of energy depends so much the future of this troubled world", and the ovation which Sir Harold received at its close, as much for his courage as for the sweep of the address itself, is unlikely to be forgotten by any of those present.

Lord Robens discussed the contribution of coal with vigour and confidence, emphasizing more particularly the significance of recent developments in mechanization and organization. Mr. J. P. Berkin was equally confident as to the potential contribution of oil, and he too emphasized the technical advances in oil operations, and the scope for yet further technical advance, flexibility and adaptability. Prof. H. J. Kruisinga was confident that future developments in gas technology and the greater availability of natural gas would make for an increasing contribution to the world's needs for energy. Lord Hinton questioned, however, whether existing knowledge permitted quantitative forecasts of the contribution of hydro-electric power or nuclear power. He thought the development of hydro-electric power was likely to continue for several decades but that, in the long-term, its exploitation would diminish under the competition from nuclear energy, which he expected to lower progressively the limit of acceptable cost.

In this context, it is worth noting the lecture on nuclear power development in the United Kingdom, which Sir William Penney gave to the Japanese Atomic Industrial Forum in Tokyo and which has been published in *Atom*, the monthly information bulletin of the Atomic Energy Authority (108, 198; October 1965). Sir William's outline of British progress in the industrial application of nuclear power, showing the trend from the first magnox station to the advanced gas-cooled reactor at the Dungeness *B* station, indicated that, with a 30-year life and an average load factor of 75 per cent, the latter station would give a generating cost of just more than 0·41*d.*/kWh, or just less than 0·38*d.*/kWh with an 85 per cent load factor. He was confident that the fast reactor offered promise of lower power costs as well as of an immense improvement in the use of natural uranium. Sir William predicted that with a large programme of fast reactors, the cost of the fuel cycle would be less than 0·1*d* per unit, and in the longer term could be about half this amount. The capital costs should be similar to those of advanced thermal neutron stations built at the same time.

The most imaginative contribution to the Cambridge symposium was undoubtedly that of Prof. Ubbelohde, which nevertheless provided a wholesome corrective to some of the earlier optimism. He emphasized the extent to which the need to plan supplies of energy had outstripped the development of wholly reliable techniques of forecasting and also the importance of giving special consideration to the cost and timing of switches between different forms of energy. He reminded his audience that almost all technologically advanced communities are now net importers of energy and that hindrances to free access to energy resources outside national boundaries could become much more obstructive, with increasing danger of famine conditions to countries importing energy on a large scale. He also gave warning of the high quality of political judgment demanded in deciding the extent to which a policy of protection for indigenous production of energy is wise or desirable. He emphasized the importance of ensuring that the methods used to modernize an old industry do not unduly distort invention and design in technological innovation in the newer industries.

Prof. Ubbelohde also observed that until recently the spontaneous urge towards technological advance had been most marked in communities living in climates in which subsistence is neither very easy nor very difficult. He suggested that we might well ask if any of the more advanced nations as yet showed any signs of levelling off in the rapid growth of their *per capita* consumption

* Ministry of Power. *Fuel Policy*. Pp. iii+35. (Cmnd. 2798.) (London: H.M.S.O., 1965.) 3*s*. net.

of energy. If restraining factors were beginning to be felt, it was important to try to describe their nature. Such a question might well be raised about Britain, whose earlier start in technological growth could now be a handicap.

Prof. Ubbelohde's reference to the power technology of the future, including the direct conversion of nuclear energy into electric power, the use of fuel cells, the generation of electricity by magneto-hydrodynamics and the possibility of approaching more closely the vastly more efficient biological power mechanisms, is obviously too visionary to have any practical bearing on the White Paper. This does not apply, however, to what he said about the process of policy-making. The whole implication of his address is that much more needs to be done to improve the process of decision-making and enabling decisions to be based quickly on all the relevant facts. This criticism is implicit in the P.E.P. Broadsheet. The White Paper on *Fuel Policy* does nothing to remove the gravity of the charge in spite of the claim at the outset that the Government has improved and extended the arrangements for securing the effective and co-ordinated development of coal, petroleum and other sources of fuel and power in Great Britain, and of promoting economy and efficiency in their supply, distribution and consumption.

The Minister of Power describes the arrangements for consultation and co-ordination between these industries, particularly the Co-ordinating Committee and the Energy Advisory Council established in January 1965. His White Paper includes a paragraph on research, in which he repeats his statement in opening an exhibition at Cambridge, sponsored by the British Association for the Advancement of Science, that the nationalized industries of coal, gas and electricity are now spending more than £14 million a year on research and development, compared with £6 million in 1958–59. Their research programmes are reviewed by the Minister's Advisory Council on Research and Development, which considers: (1) whether the programmes of research are adequate to the needs of the fuel industries and of consumers; (2) whether there is proper balance between the different lines of research; (3) whether there are any gaps, undue overlapping or lack of co-ordination between the programmes of the different industries and between them and other programmes, including that of the Atomic Energy Authority, in the field of fuel and power. The Minister of Power has also a special responsibility for the research on problems affecting the safety and health of mine-workers which is carried out by the National Coal Board and by the Safety in Mines Research Establishment, under the supervision of the Safety in Mines Research Advisory Board. There is also informal co-operation in research generally between the nationalized fuel industries at all levels. In addition, on the Government's initiative, the Research Liaison Committee of the National Coal Board and the Central Electricity Generating Board has been expanded to include the gas industry.

Even the most appropriate structure or efficient organization, however, does not amount to a policy, nor does the Minister's frank recapitulation of the difficulties which confront the reconciliation of the conflicting claims of gas, coal, electricity and oil indicate what action he could take, still less proposes to take, to rationalize the fuel situation. Without decisions, however, policy is impossible. A disappointing feature of the White Paper is the Minister's evident reluctance to use his powers even in minor matters where friction arises between the gas and electricity industries. If the Government believes that the two industries should reach an acceptable agreement, policy should encourage if not enforce such agreement. Nor is the paragraph on amenity considerations reassuring, in spite of the statement that the Government is encouraging the research efforts of the electricity industry and the cable manufacturers to reduce the cost of underground transmission. It is recognized that reduction of pollution from the emission of sulphur involves greater expenditure, as does the use of underground cables instead of overhead lines. It is not recognized that this expense should be a national and not a regional or local charge, but such a step is essential in any really national policy.

The failure to deal with the investment problem is more serious, and the magnitude of the economic implications is no excuse for ignoring the issues. They are emphasized as much by the possibilities in the production of nuclear power to which Lord Hinton and Sir William Penney referred as by the new prospects of oil and gas from the North Sea. Decisions on taxation policy are involved to which the P.E.P. Broadsheet referred, but the Minister o Power comes no nearer to considering the possibility that there might be sound reasons for encouraging the use of gas where it can be a substitute for electricity than the admission that it may be desirable to curb the demand for space-heating by direct-acting appliances because of the high costs to the economy which are generally involved compared with other forms of space-heating. Nevertheless, Mr. Lee omits to notice either that the demand he thinks desirable to curb involves an investment in power stations of £2 million a day, or the bearing of cheaper energy on Britain's economic development.

To read the White Paper alone is to appreciate that as large a share of the responsibility for the position which the early onset of wintry weather precipitated rests fairly on the Minister of Fuel, including his predecessor in office, as on the fuel industries themselves. Admittedly, as the White Paper acknowledges, while there is little change from year to year in some basic characteristics of the fuel industries, yet their research and development effort continually opens up new opportunities and presents new problems. New sources of fuel supplies are being discovered, and the balance of costs between different fuels changes continually. This, however, only enhances the need for sound judgment, especially where social as well as economic costs are concerned. Nor is it easy to take decisions when, as so often happens, the interests of particular sectors are pressed with complete disregard of the wider perspectives.

The objectives of fuel policy as set forth in the White Paper are reasonable and are consistent with much in the P.E.P. Broadsheet. It is recognized further that some of the objectives desiderated are mutually inconsistent and that the single-minded pursuit of the supply of every fuel at the lowest immediate price would not necessarily be to the best advantage of the nation. As to how this dilemma is to be resolved or what should be the choice of priorities, there is no hint. Similarly, there is no indication of the resolution which will be required to pursue any policy that may be chosen. It may be that, as P.E.P. suggests, the right policy for Britain is to attempt to achieve the chosen degree of support for British coal at the lowest possible cost and with the least distortion of other resources throughout the economy. Nevertheless, the Minister and his Advisory Council must, at the same time, make the closest possible investigation not merely of the reliability of the latest tenders for

nuclear power stations but also of the implications of the developments in fast reactors emphasized by Sir William Penney. Only in this way can full advantage be taken of what is now one of Britain's foremost assets—her trained manpower and the technology it provides.

ON HUMAN BONDAGE

The Technological Society

By Jacques Ellul. Translated from the French by John Wilkinson. Pp. xxxi+449+xiv. (London: Jonathan Cape, 1965.) 63*s*. net.

IN his foreword, R. K. Merton claims that in *The Technological Society* Ellul formulates a comprehensive and forceful social philosophy of our technical civilization. The book is much more accurately described as a rigorous, detailed and persuasive analysis of contemporary civilization. Philosophically it adds nothing to Bavink's discussion of the philosophy of technology more than a generation ago in *The Anatomy of Science*, and virtually the problem of values and judgments of value is ignored by Ellul. Its counterpart is rather Mannheim's *Diagnosis of our Time*, from which, however, it is poles asunder, and it is for its searching, incisive, ruthless analysis of the impact of technology on society and of the changes that are in consequence taking place not merely in industry but in society, in government and in science itself, that this picture of what might perhaps be described as the decline of man has certain claims to be considered a major book of our times. Its prose is as lucid as its thought; the freedom from jargon matches its honesty of thought, and the translator has admirably reflected the incisiveness of the original. Whether we accept entirely M. Ellul's argument, whether or not he is right in his main contention, this is a challenging book which compels us to look below the surface and see where we are going. Any fallacies are to be detected only by hard thinking, and i he is in fact too pessimistic, he stimulates the constructive thought that is required to provide the answers.

M. Ellul's use of the term 'technique' does not make for easy reading, and is the outstanding exception in a book that can otherwise be read with ease and pleasure, due also to the high standard of production; unlike so many expensive books to-day, it is good value. By 'technique' M. Ellul does not mean simply this or that procedure for attaining an end: it is rather the sum o methods rationally reached and efficient (at a given stage of development) in every field of human activity. Accordingly, it is continually new and has no common concern with techniques of the past. Such a definition is sufficiently at variance with the ordinary more restricted concept to be liable to cause confusion, particularly when considering its effects on social relations, political structures or economic phenomena, unless the distinction is kept carefully in mind.

In the first of his five main subjects, M. Ellul elaborates this conception and traces briefly the historical development of techniques, though to a less extent than Mumford in his great trilogy, and with less assurance. In the second chapter he reviews the way in which technology functions in society to-day and the tendency of techniques to dominate the situation and of ends to determine means. In the third chapter, he carries this analysis into the economic sphere and shows how this same process holds there, thus agreeing with Galbraith's analysis in *The Affluent Society*, but not pursuing Galbraith's criticism. The fourth chapter, on technique and the State, examines ruthlessly the implications of this process in the sphere of government, particularly for democratic systems and for the relations between science and public policy, while finally in his fifth chapter, on human techniques, he extends his analysis to the implications of technique not simply for human relations in industry or problems of leisure, but to the long-term effects of television, radio and the cinema on the outlook and the very nature of man. Only in the eight pages of his final chapter does he permit himself a brief look at the future.

It is unfair to an outstanding and cogent diagnosis merely to describe it, though quite accurately, as depicting man as dominated by the machines and the organization he has created, losing more and more his power to control events, even his individuality and his creative powers, until ultimately the great machine and organization run down to a halt, unless some chance first sparks off the total destruction of a nuclear war. Admittedly also he has no place for moral values or judgments: civilization is seen first and foremost as a civilization of means which are in reality more important than ends. Nor does he offset his pessimism by offering solutions to the problems he raises, beyond insisting that correct diagnosis is the essential prelude to treatment.

The calibre of the book is illustrated much more fairly by indicating the particular challenges it presents, though obviously only a few can be mentioned as representative. For example, in this picture of technique, the choice of techniques is increasingly automatic and man is stripped of his faculty of choice, while every technical activity is superior to any non-technical activity. That is of a piece with the opposition which Ellul sees between technique and Nature, but rejection of that view and its implications calls for some deep thinking and not mere superficiality. Again, technique is seen as inconsistent with the freedom of man and no democracy is possible in the face of a perfected economic technique. He writes that technique cannot tolerate the gropings and slow tempo of science, and that it seems impossible that independent research can survive in such a technological society as he describes.

There is a thoroughly realistic passage in which the implications of this theory for scientific policy are clearly indicated and the anti-democratic character of economic technique, though he never mentions either 'scientific adviser' or 'scientific policy'. The emphasis is on the loss of liberty involved in the ascendancy of technique. He discusses the implications of human techniques and suggests that it is impossible to speak of a technical humanism, and he brings before us much that every one of us can recognize as happening. The question is inescapable: Is this where we are really going?

But not everyone will accept without further enquiry that there is no alternative, nor is M. Ellul explicit on the point: this is what could or will be, he writes, not this is what must be. His diagnosis is likely to provoke fresh battle over issues in which von Hayek and Polanyi and others have contended in the past and it would seem to be part of Ellul's purpose to stir fresh debate and enquiry. In this long book there is not a single reference—only a considerable bibliography. The reader is left, for example, to search through Mumford's trilogy for the passages to which Ellul refers, nor is the third and most relevant volume of the trilogy cited in the bibliography. There are some other surprising omissions—the work of Bavink, already noted; and the absence of references in the text is scarcely to be excused by the naïve remark that the books cited are to be read and not consulted.

That is a major blot on an important if not a great book. It is stimulating and suggestive, as provocative as Skew at his best, especially in the opening chapter, but even Mr. Wilkinson's limpid prose scarcely makes it a refreshing book, except perhaps in contrast to the stilted jargon in which so many technological and sociological books are written. This is, in truth, evidence, which Ellul has neglected, that men and women are seeking—and need—a worth-while view of life, that the spirit of man is not yet quenched, that the scientist will not be content to see the very conditions in which scientific work is possible disappear without a struggle, that mankind is beginning to become aware of its peril. To rouse men to

their danger was indeed Ellul's purpose in writing the book: had he considered more deeply Bavink's emphasis on the element in technology of fitness for a purpose he might have written a less pessimistic and a more constructive book. R. Brightman

INTERNATIONAL ENCYCLOPEDIA OF SCIENCE

The International Encyclopedia of Science

Edited by James R. Newman. Vol. 1: A to D. Pp. ix + 1–342 + plates 1–26. Vol. 2: E to L. Pp. v + 343–688 + plates 27–49. Vol. 3: M to R. Pp. v + 689–1034 + plates 50–70. Vol. 4: S to Z. Pp. v + 1035–1379 + plates 71–84. (Edinburgh and London: Thomas Nelson and Sons, Ltd., 1965.) 252*s*. the set.

The International Encyclopedia of Science is a handsome work of four large volumes, totalling nearly 1,400 pages. It is produced in first-rate American style with excellent printing, colour diagrams and photographs and many other illustrations in colour. It was first published in the United States as *The Harper Encyclopedia of Science* in 1963, and now appears, with some additional material, printed in Edinburgh with the original American spelling. At 3 guineas per volume, the price of this valuable work cannot be considered excessive.

Four hundred and fifty scientists and engineers have contributed nearly 4,000 articles which appear in the work. An encyclopaedia, almost like an anthology, is a work of compromise, selection, preference and taste. There are bound to be space limitations no matter how large the project. One may say of the work, like Samuel Johnson of his *Dictionary*, "In this work when it shall be found that much is omitted, let it not be forgotten that much likewise is performed".

The scope of the work is wide and includes all the so-called pure and applied sciences. The mathematics sections are particularly full, even to the extent of some overlapping with one another, when separate authorities write the articles in which there is some common material.

The standard of difficulty of the *Encyclopedia* varies from subject to subject: generally it is of undergraduate level or less, and much of it would appeal to the sixth-former. The intelligent layman and woman will find these volumes admirable as bedside books, although some of the mathematics, albeit logically set out, is not easy and often is of greater difficulty than the rest.

In so large and comprehensive a work, it would be easy and priggish to make criticisms in detail. There is a sizeable article on quaternions, but, of a class of thirty mathematics graduates in one British university, only one knew what they were, and even he could not suggest any applications of them—nor indeed does the *Encyclopedia*.

There is no article on the laser and even the paragraph on the maser does not give a worthy explanation of its action.

In the statistics section, average family income is given as that of the median family in the income hierarchy, and this would be true only if incomes were distributed normally or symmetrically.

More might have been said about entropy and degrees of freedom, both of which have wide applications in the sciences.

Acoustics is dealt with as the physics of sound and not the science of hearing, although there is a separate article on sound. Some of this is rather old-fashioned in conception; for example, the idea that harmonics define a tone quality.

There is an article on π which mentions its irrational but not its transcendental nature, though this is not forgotten in the article on '*e*'. Chemical research is the subject of an article which overlaps with other chemical entries, but there is no article on physical research. In an American publication, it is delightful to find that the American gentleman of fortune, "Rumford, Benjamin Thompson, Count", is described as a British physicist, as indeed he was, among other things! The pituitary body (an endocrine gland) is given an article, but there is no mention of its other name, 'hypophysis'. Lindberg is incorrectly given as the first man to fly the Atlantic.

Although one may feel sorry for writers and compilers of scientific encylopaedias, since much of their work becomes of historic interest only, because of the rapid progress of the subject, there is much in these volumes which will not quickly become effete. Moreover, it can be expected that another edition will be called for very quickly, because of the scope and worthiness of the present work. In this case, a 'tidying up' of the *Encyclopedia* will produce an even better set of books. Large as are these four volumes, 1,400 pages are a not great amount of space to encompass, even briefly, the whole of scientific knowledge. Some of the articles, such as those which deal with pure mathematics, statistics and quantum theories, should be read by future editors, so that common material between the parts of these (and other) subjects respectively might be eliminated. Some of the smaller articles could be combined into larger treatments of the subjects and references made thereto under the present headings. This would save space for more comprehensive essays on some important topics about which little appears in the present volumes.

The many pages of tabulated information, the bibliographies and the index are excellent. The whole is generally a splendid piece of work. W. L. Sumner

INSECT NERVOUS SYSTEM

The Physiology of the Insect Central Nervous System

Edited by J. E. Treherne and J. W. L. Beament. (Papers from the 12th International Congress of Entomology held in London, 1964.) Pp. ix + 277. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 60*s*.

The Physiology of the Insect Central Nervous System is a collection of fifteen articles based on papers presented at the twelfth International Congress of Entomology, and it is not surprising that it is a mixed bag, ranging from original contributions of interest mainly to the neurophysiologist, to reviews of recent work which are of interest to the general reader. It includes the following topics: properties of the axon (Narahashi); composition of the fluid bathing the neurones (Treherne); ultrastructure of synapses (Smith); free amino-acids of the central nervous system (Ray); neurophysiological mapping and pharmacological study of a ganglion (Bernard, Gahery, Callec and Boistel); co-ordination of reflex activities (Weevers, Wilson, Miller and Rowell); neuronal pathways (Hughes); recordings from single neurones of optic lobe and brain (Horridge, Scholes, Shaw and Tinstall); learning in headless insects (Hoyle); and stimulation of areas in the brain concerned with control of sound production (Huber).

The articles by Narahashi and Treherne review their own recent work on the nerve impulse and show that the insect has fluid of an ionic composition differing from that of haemolymph bathing the axon and that the nerve-impulse follows the classical pattern. Smith points out that axons which are closely apposed may have no glial material between their membranes, and he regards this situation as a pre-requisite for a synapse. It is of interest to speculate on the possible function of such presumptive synapses which are found in both central and peripheral systems. In his review of neuronal pathways, Hughes gives in a concise form an excellent account of method-

ology and discovery in this field. For the reader who is interested in locomotory mechanisms the articles by Weevers, Wilson and Rowell give an up-to-date account of recent developments. Miller's account of the control of spiracular movement is particularly lucid and stimulating.

Although Hoyle's paper is not a review but a substantial original contribution, his conclusion that Horridge was justified in using the term 'learning' to describe behaviour in headless insects is of wide general interest. Hoyle demonstrates at the neurophysiological level the phenomenon of 'reinforcement' at the behavioural level. His preparation is the simplest at present available for the study of the physiology of learning. The suitability of insect preparations for neurophysiological work depends partly on the separation of constituent parts of the nervous system into ganglia and peripheral neurones, but particularly on the small number of central neurones involved. The insect achieves with a few cells what the vertebrate uses many cells to accomplish. The spiracular muscle preparation of Miller is another with a considerable future in the analysis of central mechanisms, particularly the role of the median ('autonomic') system. The preparations of Rowell, in which he progressively isolates the prothoracic ganglion, illuminate the apparently widespread phenomenon of non-specific inhibition. The classical type of localization experiment is well exemplified by the work of Huber in locating by stimulation those 'centres' of the brain concerned with sound production. The caterpillar stretch-receptor preparation of Weevers with its single sensory neurone also provides an easily recognizable input to the central nervous system.

This book shows clearly that a variety of techniques is necessary for studying the physiology of the nervous system, but above all it shows the necessity for a sound anatomical basis in physiological work. As Roeder points out in his epilogue, the first gap is in 'old-fashioned' neuroanatomy. It is good that physiologists realize that anatomical studies are indispensable to future progress. Let us hope for a rise in the status of anatomists and histologists, to attract research workers of the necessary calibre.

L. H. FINLAYSON

LEVIATHAN AND CO.

Marine Mammals

By R. J. Harrison and J. E. King. (Hutchinson University Library.) Pp. 192. (London: Hutchinson University Library, 1965.) 15*s*.

MARINE Mammals packs a remarkably complete account of the cetaceans, pinnipeds and sirenians into 200 pages. The very inaccessibility of these creatures, which differ in so many ways from their terrestrial relations, enhances their interest to the zoologist and throws out a challenge to investigate the manner of their lives.

Until about 25 years ago the only methods that could be used for learning about them involved observing living animals in their native habitats, often difficult of access, and dissecting their dead bodies either fortuitously washed ashore or obtained in the field and transported in a more or less mutilated condition to the laboratory. Now the invention of aqualung diving allows the zoologist to approach them in their own element; developments in electronics permit a study of their remarkable underwater powers of echo-location; and the building of the great marine aquaria, the 'oceanariums', has brought the cetacea as well as the pinnipeds and sirenians into captivity where they can be kept under close observation and be made the subject of experiment.

So much has been discovered by these means about the marine mammals that Man has basely tried to enlist their help in his futile quarrels—attempts have been made, misusing the newly acquired knowledge, to train dolphins to find out and advertise the presence of enemy frog-men spying on harbour installations and perhaps trying to destroy them, and so act as unwitting suicide 'heroes' by homing on enemy underwater craft while carrying charges of explosives to sink them.

The authors give a concise account of the systematics of the three orders of marine mammals, and enumerate the species with notes on their appearance, habitats, geographical distribution, and frequency of coming under the notice of Man. Under the modest headings of "Some Characteristics of Cetacea" and "of Pinnipedia" a very good account is given of the biology of the creatures in all its aspects, anatomical and physiological, together with notes on their general natural history. Little that is known about these fascinating creatures escapes notice, although it is necessarily summarized and the information is compressed.

The book is well written and can be read from cover to cover with enjoyment and profit, but it is also a valuable work of reference, for an extensive bibliography cites the more detailed sources from which much of the information is culled. There is a good index, and the pages are embellished with a series of drawings by Mr. Frank Price of the animals and their anatomical details; but what has happened to the eye of the sperm whale, which seems to have migrated to a very unusual position—perhaps it is the roving eye of Moby Dick? This book is a distinguished addition to an already distinguished series.

L. HARRISON MATTHEWS

PROPHYLAXIS AGAINST RADIATION INJURY

Chemical Protection Against Ionizing Radiation

by Prof. Zenon M. Bacq. (A Monograph in The Bannerstone Division of American Lectures in Living Chemistry.) Pp. xvi+328. (Springfield, Illinois: Charles C. Thomas, 1965.) 14 dollars.

THE search for prophylactics against radiation lethality in mammals, begun in the late nineteen forties, has proved unrewarding in that no agent having practical utility has emerged. Nevertheless, as Prof. Bacq reminds us early in *Chemical Protection Against Ionizing Radiation*, it is true that: "Chemical protection has won an enviable place in the vast ensemble of radiation research; it occupies about ten per cent of the time and the publications in congresses, meetings and periodicals dedicated to radiation research". For most, interest now lies chiefly in the properties of existing agents, rather than in the search for new; in their pharmacology, biochemistry and mechanisms of action at one or more levels of biological organization. With its ramifications into many disciplines, there is no disputing with the author that: "chemical protection . . . has become a very complicated subject in recent years". He has produced this book "because a guide written by somebody who has actively lived through its capricious evolution might be useful to those who are engaged in or want to enter one sector of this research field".

Prof. Bacq is to be congratulated for this attempt to bring the mass of published observations on this subject into order within the covers of a single volume, a task for which his long association with the subject fits him well. In this task he has been, in the main, successful. The literature has been covered largely up to 1964. Where obscurity occurs, one feels it is mainly due to the contradictory nature of the material.

In this book, the field has been narrowed down by exclusion of all but passing mention of curative, post-irradiation treatments; prophylaxis alone is considered. However, attention has not been confined to the protection of mammals. There are twenty chapters, the first

three being brief and introductory. Chapter 4 presents the major classes of radioprotectors and should be of use to beginners; it is based on a list of familiar agents impartially selected, "by an anonymous scientific secretary", for the second report of the United Nations Scientific Committee on the Effects of Atomic Radiation (1962). The remainder cover all aspects of the subject but some may be selected for comment. In Chapter 5, on pharmacology, the review of the diverse circulatory effects of thiol protectors in different species seemed of particular interest. In Chapters 6 and 7 are collated a mass of data on the metabolic effects and metabolism of radioprotectors: it is not the fault of Prof. Bacq that any definite relationship between protection by cysteamine and its tissue distribution is still difficult to discern. Chapter 9, which deals with protection against effects other than lethality, gives a useful literature survey. Examples of protection against genetic damage, in micro-organisms, are brought together in Chapter 12. In Chapter 14, possible applications of thiols in connexion with radiotherapy are mentioned and, it is hoped, will be noted. Chapter 19, on protective mechanisms, is impressive: the section on the role of molecular oxygen is, to me, a highly illuminating interpretation of an extensive literature. The final chapter is largely of a speculative nature. Some useful practical information is included, as that on dosage in Chapter 5. There is a large bibliography, and the index is adequate.

In a work of this type, some omissions and errors of detail inevitably escape correction. There are, in fact, numerous minor errors. Eccentricities in spelling such as "gasses" (page 3), "cristallized" (page 9), "sensitizors" (page 32), "exsudate" (page 65) or such forms as "methemoglobinizing" (page 44) and "aminoisothioureae" (page 67) probably do no material harm. The term "physiochemical" appears on page 79 and again on page 221. In chemical nomenclature, in Table 2 (page 17) "N-dimethylcysteamine" might disturb the chemist: N,N-dimethylcysteamine is the correct (American) nomenclature. On page 168, some units are omitted: "Just as in the intact mouse, the active concentration for MEA and AET is around 10^{-4}". If these are grams per ml., this concentration would correspond with a mouse dose of 100 mg/kg.

There can be little doubt that Prof. Bacq has accomplished his object, and that in bold, Gallic style: this work will inevitably be used by those already engaged in this field of research and by the novice. The book is handsomely produced but the price is very high, even for a modern scientific monograph, so that the private purchaser is virtually excluded. J. H. Barnes

PLANS AND AFRICA

Man and Africa

Edited by Gordon Wolstenholme and Maeve O'Connor. (A Ciba Foundation Symposium jointly with The Haile Selassie I Prize Trust.) Pp. xix + 400. (London: J. and A. Churchill, Ltd., 1965.) Cloth 36*s.*; limp 25*s.*

THE Ciba Foundation organized a conference in 1964, at Addis Ababa, on the climate, resources, development and welfare of Africa; *Man and Africa* embodies the papers and the discussions. As at every conference, the papers vary in quality; some embody the same old clichés which have done duty at conferences for the past twenty years, but most of them are factual and fresh. The participants were of many races and of many disciplines.

The geographical introduction by Last is good, in spite of the confident assertion, "We must tell them in 1964 what they must do in 1984" (p. 22). Dekker shows clearly the instability of African climate and the fact that water supply is a limiting factor over much of the continent. Goody shows how the imposition of several European languages on a variety of African dialects may hinder the unification of Africa, but there is little reference to the great ability of Africans in learning languages.

Lambo emphasized the bad effects of migration and urbanization on mental health. But can migration be stopped, when Africans love to travel and to see strange places? "Before major developments in the socio-economic sphere took place, very little was heard of addiction or abuse of drugs as a national or continental medico-social problem" (p. 135). Little may have been heard of addiction to hemp and it was illegal; but there was much of it and one often saw in the countryside the blank, bewildered faces which, alas, one sometimes sees in London. Why do people smoke hemp? The only time that I tried it, I had no erotic dreams, only heavy sleep and a bad hangover.

The paper by Sutton and the discussion on "African Educational Needs" embodies many ideas applicable far beyond that continent: "the now painfully familiar problem of primary-school leavers increasingly hopelessly seeking jobs in crowded towns" (p. 196); "African leaders now denounce the education of 'pen-pushing' left to them by the colonial powers" (p. 197); "there is, I believe, no African country which has shown in recent years a decline in the numbers of children in school. But there are several, including ones with impressive rates of economic growth, where total employment has declined" (p. 198); "Education for most Africans cannot, in the short run, be a preparation for employment. It will either be a preparation for unemployment or for some form of self-employment, mostly agricultural" (p. 200); "it is not easy for young graduates to regard their talents humbly or to appreciate that they may not yet be of much use to society" (p. 205); "Some of those returning from abroad are even unable to work for two or three years afterwards" (p. 216); "Often more than half the high cost of teaching university graduates goes on almost palatial dormitories" (p. 217); "an elite group which may be irresponsive to the national needs and insensitive to the general feelings of society" (p. 218); "Very often in a village one sees schoolboys on holiday sitting around in apathetic idleness" (p. 221).

Haldane's observations on biological research, founded on experience in India, apply closely to Africa; research can be cheap, for all that is needed is power of observation, a truthful mind and freedom from the 'there-is-no-knowledge-but-I-know-it' attitude of some graduates. Good research can be carried out by people with little education; many years ago I taught an African schoolboy of sixteen to weigh coffee samples, and it took him five days to find why his records did not always correspond exactly with my checks—that if he weighed the coffee beans early in the morning, they weighed more than in the afternoon; he did not know the word hygroscopy, but he discovered it.

"Perspectives for Industrialisation in Africa" by Ewing and Patel reads like a piece of science fiction; because production in developed countries increased 44 times in 110 years, that of Africa will increase 25 times by A.D. 2000 (p. 308); steel production will be 100 million tons, "There is no reason why African production should not attain this level" (p. 313). Some of those born in Africa had a more realistic outlook, "The demands of the African family system sometimes make it difficult for ministers and other responsible persons in government to appoint the best men to positions of managerial control, even if they are available" (p. 322); "yet, when I listen to my economic colleagues talking, I feel that the human element is really lacking" (p. 336).

Dr. Wolstenholme was obviously delighted with the great success of the conference, and he is to be warmly congratulated on it, as are the printers, for the book has good paper and the print is extremely clear and well spaced. This book is to be recommended to all those interested in African development. A. S. Thomas

POSITIONS OF RADIO SOURCES DETERMINED BY THE INTERFEROMETER AT THE ROYAL RADAR ESTABLISHMENT

By R. L. ADGIE and H. GENT

Royal Radar Establishment, Great Malvern, Worcestershire

THE determination of the position of radio sources with very high precision is one of the most pressing needs in radio astronomy: accurate positions provide the essential bases for the identifications of radio with optical sources. The calculation of the distance of a source is dependent on the optical determination of its red shift, and the whole knowledge of the radio power emitted by sources, as well as the relation between optical and radio counterparts, depends on reliable identifications. The deduction of properties bearing on the evolution of galaxies and cosmology, and of the energy of radio sources which for certain quasars and strong radio galaxies has so far proved inexplicable in terms of known physical processes, emphasizes the vital importance of identifications, and this demands extreme accuracy in determining radio positions. The interferometer at the Royal Radar Establishment (R.R.E.) has been applied to this task for the past 2 years, and we now present accurate positions of 137 small-diameter radio sources measured with this instrument.

The R.R.E. Interferometer[1] consists of two steerable paraboloids, 25 m in diameter, mounted on movable carriages. To obtain the greatest resolving power for these measurements the aerials were placed at the maximum separation of 750 m. Two separate sets of observations were made using a base-line oriented approximately east–west to measure the right ascension and near north–south to measure the declination, each source being observed for a few minutes near meridian transit. The receiver was tuned to 610 Mc/s giving a lobe-width of 140 sec of arc at this spacing (with the north–south orientation the base-line is foreshortened for directions away from the zenith, increasing the lobe-width up to 280 sec of arc for a source at the lowest observed declination of $-5°$).

Sources with a small angular diameter were selected mainly from the *Revised 3C Catalogue*[2], a few additional ones being taken from the original 3C (ref. 3) and the *CTA Catalogues*[4]. The sources were also observed with a much smaller spacing of about 150 m to resolve the lobe-ambiguities that can arise with the wider spacing where the published position is not sufficiently accurate. In addition, these observations gave a value for the unresolved intensities, which were then compared with the values obtained at the wider spacing to check the angular diameters. The position of the 'centre of gravity' of a source should be obtained with reasonable accuracy provided the amplitude at the wider spacing is greater than half the unresolved amplitude; with a lobe-width of 140 sec of arc this imposes a limit of 60 sec of arc diameter for a single gaussian source or 40 sec of arc separation for a double source. If the amplitude is less than half, the position is still valid if the source is symmetrical about the centre of gravity, but without a detailed picture of the structure the result is obviously less significant.

The interferometer was calibrated by observing sources that had been identified with optical objects having accurately known positions. This problem has already been dealt with in a previous article[5] presenting the results for eighteen calibrators. A few of these sources showed a significant difference between the radio and optical positions, in particular 3C 286, but in this case the discrepancy has now been removed by the discovery of an error in the published optical position[6]. In two cases, 3C 254 and 3C 298, new identifications as quasi-stellar sources were suggested on the basis of the agreement between the radio positions and stellar objects[7]; these identifications have since been confirmed by examination of the optical spectra of these objects[8,9]. The differences for the other sources were explicable in terms of their large angular diameter and complexity.

With many more sources now identified[6,10], a fresh calibration of the interferometer has been made. In addition, more accurate ionospheric data on the total electron content[11] have given slightly modified refraction corrections, and a re-measurement of the delay cable has meant some small changes in the declination results. The revised positions for the original eighteen calibrators differ slightly from the published results[5], but the changes are within the stated errors of measurement and in no way modify the conclusions concerning the identifications.

The measured positions of 137 sources are given in Table 1. The root mean square errors have been compounded from errors due to phase instability in the equipment, calibration, and the confusion produced by other weaker sources in the aerial beam. Errors due to random noise on the records are negligible. By careful design and temperature control of the equipment and cables, a phase stability corresponding to less than 1 per cent of the lobe-width has been achieved over a period of a few days. The root mean square value of the confusion in directions away from the galactic plane was measured and found to be 0·5 flux units, corresponding to a positional error of 2·6 per cent of a lobe-width for a source of 3 flux units (1 flux unit equals 10^{-26} W.m^{-2} (c/s)$^{-1}$).

The last column in Table 1 gives the flux densities obtained at the closer spacing scaled to the absolute values given by Conway, Kellerman and Long[12], the root mean square errors being a combination of stability, calibration and confusion errors. The observed values have not been extrapolated to zero spacing and so will not include the contribution from any large diameter halo (as, for example, in the case of 3C 84). Finally, those sources are noted which give an indication of being resolved at the wide spacing, as these positions may not represent the true centres of gravity.

Accurate positions in both co-ordinates were determined for 122 of the sources. Of these, 72 have been identified and the optical positions measured to an accuracy of a sec of arc or better[7,9,10]. The differences between the radio and optical positions for these identifications are given in Table 2, the sources being divided into two groups, thirty quasi-stellar sources and forty-two radio galaxies. Each difference (expressed in sec of arc) is the total separation between the two positions; the associated error (root mean square) is the resultant error in total separation calculated from the radio right ascension and declination errors alone. All values have been rounded off to the nearest sec of arc for the sake of clarity.

Of the two groups, the agreement is least satisfactory for the radio galaxies, but this is doubtless due to their

larger radio angular size and not to incorrect identifications.

Considering the quasi-stellar sources alone and excluding 3C 273 (known to be a double radio source with 20 sec of arc separation[13]), 25 out of 29 sources (86 per cent) have differences less than twice the quoted root mean square errors. It is possible that the differences for the four remaining sources are real, as in the case of 3C 273. The mean difference is only 3 sec of arc, which substantiates the accuracy of the measurements and confirms the estimate of the errors involved in the radio and optical determinations.

The other conclusion that can be drawn from Table 2 is, of course, the confirmation of the validity of these

WHY IS AN ODOUR?*

By R. H. WRIGHT
British Columbia Research Council, Vancouver 8, Canada

A SMELL is a sensation we perceive when odorous molecules impinge on sensitive nerve endings in our noses. There are three important things about smells. The first is that the nose is the most sensitive chemical detector known: at its best, its threshold of perception is more than one hundred times lower than the best of our gas chromatographs. Secondly, smell sensations are highly specific: most of us can easily distinguish cigarette smoke from cigar smoke or a rose perfume from a violet scent, but an experienced perfumer can do much better, so that, for example, there are men who can not only name the country of origin of a sample of lavender oil, but can even name the farm from which it came. The third important thing is the emotional impact of a smell. The trade in perfumes is based on this, and even such unromantic objects as second-hand cars can be given an added market value by an artfully applied 'new car smell'.

From a scientific point of view, the sensitivity and specificity are the most interesting, though I will have something to say about the emotional import later on.

Prof. J. T. Davies, in the University of Birmingham, has developed a theory of the olfactory threshold that allows him to calculate the approximate threshold concentration of many odorous substances from two basic parameters[1]. One is the partition coefficient of the substance between air and a water–oil interface. The other is the cross-sectional area of the odorous molecules. According to his theory, the partition ratio determines how many odorous molecules will collect on the receptor surface, and the contact area in some way (which he does not try to explain) determines their ability to 'puncture' the nerve cells and initiate action potentials which travel to the brain.

Davies's theory gives very good quantitative threshold values, but it says nothing about the quality of the sensation. It does not tell us what makes one smell different from another.

Thus, we know some of the properties of substances that relate to their odours but not others. For example, a substance that is completely non-volatile can have no odour, but volatility alone is not enough—some degree of lipid solubility is also needed. Moreover, a substance that is very acidic or very basic, and one that is strongly oxidizing or reducing, is likely to generate a sensation of pain because of its chemical reactivity, and this will usually hide any true odour it may possess.

The properties of a substance that are related to its smell are called its 'osmic properties', and the position to-day is that the osmic properties that have been identified are the non-specific ones. They do not correlate with particular odours such as those of rose, or musk, or peppermint. The fact is that the osmically specific properties of odorous substances have still not been securely identified, and until they have been, we will not be able to give a really precise answer to the question "Why is a smell ?".

To identify the osmically specific properties of odorous molecules, we must look for secure correlations between certain molecular properties and the olfactory sensations that go with them. A great many correlations are conceivable, but most of them have not stood the test of experiment. At present, two, or possibly three, lines are receiving the most attention.

I would like to mention first the 'Profile—Functional Group' or 'PFG' theory put forward some years ago by Dr. M. G. J. Beets in Holland[2]. He supposes that the particular kind of sensation a molecule evokes is determined by the interplay of two factors. These are: the overall shape or 'profile' of the molecule, and the 'functional group' that acts as a point of attachment and so determines which of its various profiles the molecule presents to the receptor surface (Fig. 1). This is evidently a refinement of Davies's ideas since the cross-sectional area of many molecules would vary according to the direction from which they were viewed.

Dr. J. E. Amoore in California has carried this idea still further in his stereochemical theory. Originally, he supposed that the sensitive receptor surface was provided with 'pits' or 'sockets' of several rather rigidly defined shapes that only certain molecules could fit into[3]. More recently, he has abandoned this idea in favour of a specific 'silhouette' very much like Beets's 'profile' but much more clearly expressed[4]. Instead of constructing a solid model of the receptor site into which molecules with a 'floral' or 'minty' odour will fit more or less well, he now selects one molecule as typifying each odour class (floral', 'camphoraceous', 'musky', 'minty', and so on). He then uses a system of shadow matching to measure the similarity in shape between the standard molecules and other

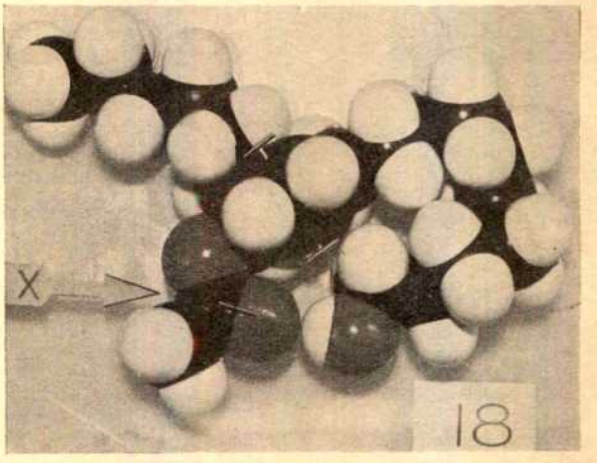

Fig. 1. Model of an analogue of the sex attractant scent molecule of the gypsy moth. The 'profile' it presents to the receptor surface is highly dependent on which 'functional group' governs the orientation

* Substance of an address to the annual meeting of the Pacific Northwest International Section of the Air Pollution Control Association, November 3, 1965.

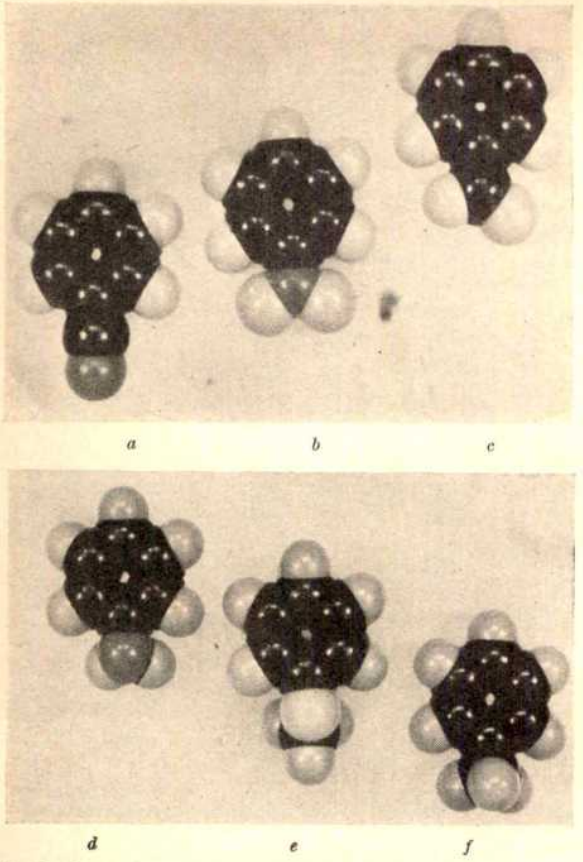

Fig. 2. Benzonitrile (*a*), nitrobenzene (*b*) and benzaldehyde (*c*) have quite similar odours, but their profiles are no more similar than those of aniline (*d*), anisole (*e*) and toluene (*f*) which have distinctly different odours. Vibrational blurring of the edges would still further reduce the differences in shape

molecules when the silhouettes are superimposed. He uses photographs of three-dimensional models taken from three different directions to make the silhouettes, and he finds some degree of correlation between the profiles of substances the odours of which are in a general way similar to the various standard odorants.

The stereochemical approach has received much very favourable comment, and is at present regarded by many people as the most promising line of investigation. The principal objection to it is its inability to account for the remarkable specificity of odour sensations. Thus, Amoore lumps together under the single heading of 'floral' such disparate odours as geraniol (rose-like), anisole ('aniseed'), ionone (violet) and terpineol (lilac-like). The more or less substantial differences in smell within his group of generally 'floral' odours would indicate that the molecular profile is osmically specific only to a very rough approximation (Fig. 2).

The third of the present lines of attack aims at pinpointing the osmically specific properties with precision by identifying them with particular vibrational movements of the odorous molecules.

From a vague beginning more than a hundred years ago, when Faraday and later Tyndall speculated that odour might be associated in some way with molecular vibrations, the theory has become more and more specific with the passing years. The first major advance occurred 30 years ago when Sir Malcolm Dyson suggested that the then recently discovered Raman effect made it possible to give numerical values to the vibration frequencies of molecules, and so, for the first time, opened the way to an exact correlation of particular odours with particular patterns of vibration frequencies[5]. Very little development occurred until about 10 years ago, when I pointed out that the osmic vibrations must necessarily be low-frequency ones[6]. This is because they alone can acquire the necessary quanta of energy from the rather soft collisions which molecules make with each other at room temperature (which is only 300° C away from the absolute zero). Low-frequency oscillations are, however, the most difficult ones to study experimentally, and then only rather simple molecules of about the degree of complexity of nitrobenzene can be studied (Fig. 3).

Quite recently, and on the basis of some of the latest information to be published, I have found indications that not all the low-frequency vibrations of a molecule are necessarily osmically active: the active ones are probably those which involve motions that are perpendicular to the surface of the olfactory receptor organ on which the odorous molecule is lying[7].

When a molecule vibrates, each atom in it oscillates about a mean position in a very complicated way, but its motion can be resolved into components along three axes at right angles to each other. We can choose these axes any way we like, and so I like to think of two of them as parallel to the surface of the receptor organ in the nose, and the third as perpendicular to it. Then, it is only the oscillations along that third axis that appear to be osmically active and specific (Fig. 4).

This seems to be a rather important addition to the theory, because its effect is to draw together into a single focus all the various approaches I have outlined.

Thus, the role of Beets's 'functional group' is to orient the molecule in a certain way with respect to the surface and hence to determine which of its oscillations will be osmically active.

The amplitude of these oscillations is considerable. For example, calculations show that in their out-of-plane

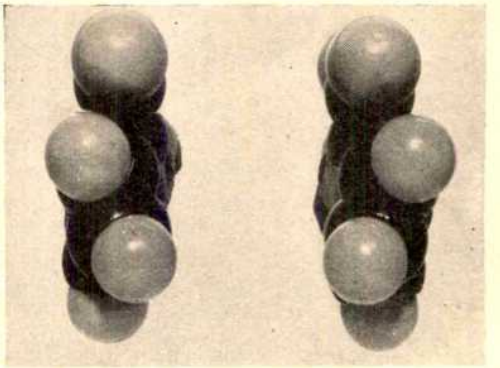

Fig. 3. Models showing approximately the amplitude of movement in one of the out-of-plane modes of nitrobenzene. Oscillations of this magnitude limit the precision with which the shapes or 'profiles' of molecules can be specified

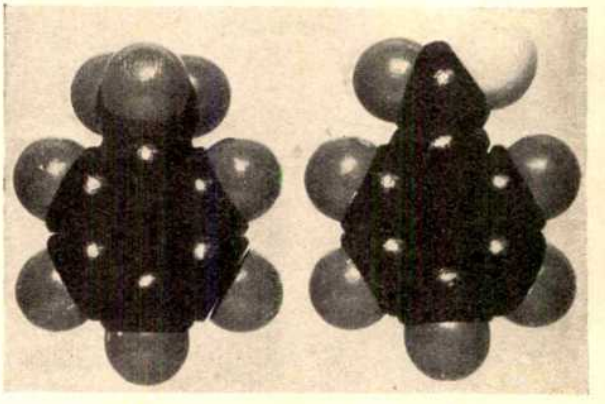

Fig. 4. Toluene (*a*) and benzaldehyde (*b*) have closely similar shapes or 'profiles' especially when the edges are blurred by vibration, but the distinct differences in their odours are paralleled by correspondingly distinct differences in the low-frequency, out-of-plane movements of the atoms in the ring

movements, carbon atoms in benzaldehyde may be displaced by as much as a quarter or a third of their diameter (that is, by as much as 0·3 Å) from the equilibrium position. This means that the molecular shape is only approximately described by Amoore's molecular silhouettes, and in reality their edges should be rather fuzzy because of the vibrations. At the same time, his basic idea gains added force if we picture the out-of-plane movements of the odorous molecule as conforming with corresponding out-of-plane movements of the sensitive surface. To conform in this way, the two molecules must have nearly the same frequencies in nearly the same places, so that the net effect depends both on shape and on frequency.

Furthermore, the interaction would be stronger the greater the area over which the motions of the odorant and the receptor coincided—which brings us right back to Davies' calculations which seem to show that (other things being equal) a very low threshold is associated with a large area of contact. The restriction of the contact to areas that fit sterically because they mesh vibrationally gives to Davies's theory the specificity it has lacked up to now.

The synchronous 'throbbing' of the odorous molecules and the receptor surface over a considerable area would permit of a much closer approach than would otherwise be possible, and hence allow a closer than usual electronic (van der Waals) bonding between them. This may be an important hint as to the kind of primary event that initiates an olfactory sensation.

One of the common objections to the vibrational theory is that the quanta of energy in a low-frequency mode are too small to be in any way effective. In other words, if it is the vibrational energy that is the important thing, there is too little of it in a low-frequency mode to be significant. This objection disappears if the energy is not the prime mover in olfactory stimulation.

Another objection to the vibrational theory is that it has appeared to presuppose a type of dipole-to-dipole coupling between the receptor and the odorous molecule that is inconsistent with quantum-mechanical principles and with some of the spectroscopic data. This objection also loses its force if we suppose that the coupling does not take place between oscillating dipoles, but is an ordinary van der Waals interaction made stronger than usual by an unusually close approach over an unusually large area of contact.

Quantum mechanical theory is concerned with transitions between different levels of vibrational energy, and is only vaguely conscious of what the molecule is doing between the transitions. In contrast, the vibrational movements that go on between transitions are the ones that may be giving various substances their specific odours. The fields of interest of the molecular spectroscopist and the odour chemist are therefore not the same. The osmically significant fact is that a molecule is vibrating, whereas the spectroscopically significant fact is that it can change from one level of vibrational excitation to another with the absorption or emission of radiation.

The complex oscillations of a molecule can be analysed into certain independently excitable movements which are called its 'normal modes' of vibration. The spectra sometimes show indications that an energy transition takes place into or out of two modes simultaneously, but spectroscopically the resulting bands are usually weak. The spectroscopists regard them as rather exceptional happenings which result from the fact that the two normal modes are not entirely independent, but are 'coupled' through what is termed their 'anharmonicity'. There is nothing to prevent two modes from becoming excited simultaneously given enough energy in the collision to do it, and this can happen whether or not a corresponding combination frequency appears in the spectra. The physical conditions during excitation by collision are completely different from those during a radiative excitation.

When a single mode is excited, the period of the vibration is the interval between successive passages through the equilibrium configuration. When two normal modes are excited simultaneously, the period of the complex oscillation is defined in exactly the same way, and its frequency is the difference between the frequencies of the two normal modes. Osmically, such a difference frequency should be just as significant as a pure normal mode of comparable population. Whether or not a corresponding 'difference band' appears in the spectra is irrelevant, because the spectroscopic transition into or out of two modes simultaneously depends on entirely different considerations.

Previous searches for 'osmic frequencies' have not taken into account the possible role of the difference frequencies that must arise when two normal modes are excited in the same molecule at the same time. When this possibility is included (something that is only now becoming possible, thanks to the advance of molecular spectroscopy), it serves to fill what would otherwise be awkward gaps in the correlations.

The vibration theory—at least since Dyson's contributions—has been unique among odour theories in being capable of precise verification, at least in principle. Whether it would be so verified in practice depends on developments in spectroscopy which are only now becoming adequate for the purpose. So far as matters have gone, the effect has been a progressive refining and sharpening of our picture of the part played by vibration in giving molecules their osmic specificity. At the same time, there begins to emerge a picture of the actual triggering mechanism that incorporates several seemingly distinct approaches to the problem. Thus, as has happened so often in the past, what appeared at first to be competing alternatives may prove to be complementary parts of a single whole. The next few years should see interesting developments in the whole field.

Interest in the matter is not merely scientific or academic. So far, I have been trying to answer the question, "Why is a smell a smell?" Now I must answer the question, "Why is a smell important?" To do this, let me first recall something that has nothing to do with smells.

Forty years ago, the populations of most of our cities were much smaller than they are now, but air pollution was much worse then than now. In those days, every house had a coal-burning kitchen range, and those with central heating had a coal-burning furnace as well, and they all poured out immense amounts of fly ash and soot. Soot was the main and, indeed, almost the only serious air pollutant. Forty years before that, dried, wind-blown horse manure matched it in importance if not in public mention. Now, what was it that has eliminated these two forms of air pollution? Was it restrictive legislation? Was it ingenious scrubbing devices? Or was it the automobile which took the horses off our streets and the gas and electric stoves which took the coal bins out of our houses?

The moral of this story is that it is better to make air pollution uneconomic and obsolete than it is to make it illegal, though this is not to say that legal restrictions are not a useful prod in the right direction.

To-day, automobile exhaust gases are the main source of air pollution in large cities, but there is another kind of pollution that affects country and city alike and is, indeed, a world problem. This is the danger from pesticide residues. Rachel Carson in her book, *Silent Spring*, pointed to a danger, but was not able to suggest a realistic solution.

At the beginning, I mentioned the emotional impact of smells. At the human level, this reflects the fact that smell is our most primitive sense. It is no longer of primary importance to us in comparison with sight and hearing, but, as we go down the ladder of living things, we find that smell plays a more and more important part in the lives of most creatures.

A very great many insects (though perhaps not all) regulate such vital activities as mating, eating and egg-laying by chemical signals that are nothing more nor less than smells. When we can understand better what scents are and how they are registered by the insects' antennae, we will be in a position to control insects by misleading them, by confusing the signals, and by exhausting their ability to respond; and the chemicals needed to do this will not be poisons. Instead, they will be smells that affect one kind of insect only, and in one special way only, and are harmless to everything else. We will be able to control one pest at a time and leave the balance of Nature undisturbed, or disturbed as little as possible.

When that stage is reached, the contamination and pollution of our environment by pesticides and pesticide residues will be as uneconomic and as obsolete as pollution by coal smoke and horse manure are now. This is one practical answer to the question, "Why is a smell important ?"

PROGRESS OF CANCER RESEARCH

THE forty-second annual report (for 1964) of the British Empire Cancer Campaign for Research*, like its predecessors, is a weighty tome of 700 pages describing hundreds of investigations carried out at the centres financed by the Campaign or working under its aegis; these researches, most of them having a direct bearing on cancer, can be classified into three main groups and will be treated separately by the three reviewers, namely, carcinogenesis and the biology of cancer (I. H.); radiotherapeutics and radiobiology (P. A.); clinicopathology of cancer (A. L. L.).

Carcinogenesis and the Biology of Cancer

In the field of carcinogenesis, Haddow has found that the glycidyl ethers induce sarcomata in rats, and Roe and colleagues, also at the Chester Beatty Institute, are working on tumour-inducing characteristics of a variety of agents such as polyvinyl sponge, contraceptive chemical preparations for use intravaginally, asbestos, hydrazine compounds such as the anti-tuberculosis drug isonicotinic acid hydrazide (INAH), thalidomide, tobacco smoke fractions and nitrosonornicotine. At the same centre Birbeck and Kerawalla have studied the progressive changes in skin-cell ultra-structure, using the electron microscope, after application of carcinogens. Boyland and associates, from a study of urethane and related compounds as carcinogens and antiviral agents, conclude that "the effect of urethane and hydroxylamine derivatives may therefore be exerted through reaction with pyrimidine bases of DNA", which greatly simplifies the situation, but where the two processes under discussion, carcinogenesis and antiviral action, diverge still remains a difficult question.

The introduction of new carcinogens continues—only to make any chemical theory of carcinogenesis less and less capable of explaining transformation from the normal to the malignant.

The excitement first generated by the lung cancer–cigarette smoking discovery has now petered out into a tortuous search for carcinogens in cigarette smoke, which is something of an anticlimax. (Why do cigarette manufacturers' research teams not look for some other way of administering the narcotic to addicts without having to supply at the same time tar, benzpyrene, etc. ? Perhaps that is precisely what the manufacturers are trying to avoid.)

At the Middlesex Hospital a comprehensive study of azo-dye carcinogenesis is under way, using electron microscopy and cytochemical and biochemical methods; the investigators conclude that the question of the binding of dye, or of a metabolite, to protein as a necessary step in carcinogenesis has not yet been settled.

Rees *et al.* at University College Hospital have been investigating intranuclear changes in carcinogenesis; contrary to the oft-quoted, but extremely naïve, statement that carcinogens bind to DNA and therefore carcinogenesis is primarily a chemical change in DNA (which ignores carcinogenic agents like plastic film), Rees concludes that "It is therefore considered that some of the nuclear changes are the result of direct alterations in nuclear metabolism and others are secondary to metabolic changes in the cytoplasm. It was also noted that there were similarities in biochemical changes in the nucleus 2 weeks after feeding different carcinogens, despite differences in histological appearance".

At St. Bartholomew's Hospital, experiments have been in progress to see if pulmonary tumour induction in mice by urethane or by DMBA can be facilitated by irradiation (400–500 r.); it was found, on the contrary, that irradiation was inhibitory to the action of urethane.

At Birmingham, Orr *et al.* have continued their study of carcinogen-induced breast and ovarian tumours in mice; in one particularly interesting experiment "ovaries from mice which were given fortnightly skin paintings of 0·5 c.c. 0·5 per cent DMBA in olive oil were capable of developing into tumours in 50–100 per cent of cases after transplantation into untreated mice whose own ovaries were removed. Even ovaries grafted only 10 days after a single painting developed tumours in three or four cases after 14 months, while ovaries grafted from untreated mice gave no tumours in ten cases 20 months after grafting. . . . It would seem that a single treatment of a mouse with DMBA sets in motion a series of events in its ovary which eventually will lead to tumour production, even when the ovaries are transferred after as little as 20 h to normal hosts. This rapid effect of a single dose of DMBA could provide a useful tool for further investigations of the mechanism of action of this carcinogen".

From the Queen Elizabeth Hospital in Birmingham comes the following cautious statement: "Steroid contraception. In collaboration with the Family Planning Association and the Council for the Investigation of Fertility Control, the Department has been screening patients on steroid therapy as a long-term project. The results of this study are in print, but it can be said that cytologically and histologically there is evidence in a small percentage of the cases of nuclear abnormalities. It is not, however, justified to undertake immediate biopsy but follow-up would seem to be vital for this group of patients. Our total number of biopsies from patients on steroid contraception is so far 15. It is already obvious, however, that within 6 months modern steroid contraceptive therapy leads to a condition of cervical pseudopregnancy. It will require between 5 and 10 years before the significance of these changes is clear and especially with regard to the incidence of pre-cancer in patients on

* British Empire Cancer Campaign for Research. Forty-Second Annual Report covering the year 1964. Part 1: The Chairman's Statement and the Accounts of the Central Organization. Pp. xxxvi. Part 2: The Scientific Report of the Researches Undertaken by the Central Organization and its Autonomous Councils in the United Kingdom, and by some of its Affiliated Organizations Overseas. Pp. xxxvii–lix + 705. (London: British Empire Cancer Campaign for Research, 1965.)

steroid therapy. At the moment we can recommend that all patients who are on the contraceptive pill should submit to regular cytological screening tests and that the 'positives' should be watched closely both by the clinician and the cytologist".

The two branches of cancer research which have attracted most attention in recent years have been the immunological approach and the study of tumour-inducing viruses; Alexander *et al.* find that implantation of heavily irradiated benzpyrene-induced tumours grown in rats confers resistance to a challenge dose of 2×10^6 cells; they conclude that the lymphocytes play an active part in the resistance to tumour cells and that they attack the tumour antigens directly.

At Guy's Hospital, Batchelor has been studying immunization in mice to epithelioma produced by dimethylbenzanthracene; and at King's College Hospital, Tee and Wang in experiments on the antigenic composition of human tumours state: "An antigenic analysis has been made of seventy-two tumours and thirty-one normal tissues using anti-tumour antisera and the agar gel double-diffusion technique. Tumour-specific reactions were observed with some tumours, regardless of whether the tumours were derived from different patients or from different sites. A higher proportion of positive reactions was observed with tumours from the same site as that of the immunizing tumour. Anti-tumour antisera did not react with the normal tissues. . . . It was confirmed that these additional antigens were not due to isoantigenic differences between the cells of genetically different individuals. Loss of antigens was shown in at least a proportion of the tumours. It was not possible to detect antigens serologically identical with the tumour-specific antigen in extracts of foetal tissues and HeLa cells". Tee and Watkins, using the analytical ultracentrifuge and gel-filtration through 'Sephadex' columns of the globulins in mice immunized with a mouse leukaemia, conclude that, "The results may suggest that the immunization has caused stimulation of specialized plasma cell clones producing a particular fraction of the 7*S*γ-globulin. Further experiments are in progress to measure the M^z/M^w ratios of the 7*S*γ-globulins from different strains of mice immunized with other transplantable tumours and to see if similar results can be obtained by immunization with other antigens, in particular transplantation antigens".

Salaman *et al.* at the London Hospital have found evidence of a new mouse sarcoma virus (MSV) in the cell-free plasma of rats with Moloney virus leukaemia (MLV); the MSV virus when inoculated in rats and mice induces solid sarcomata, angiomata and cysts, filled with clear fluid or blood, of the thighs, abdominal or thoracic walls, the flanks, axillae and lymph nodes. The sarcoma is transplantable to mice and hamsters, and the cell-free filtrate produces tumours rapidly, especially in new-born rats and mice. The virus is neutralized by mouse antisera to Friend virus (FV) and also by undiluted monkey and rabbit anti-sera against Rauscher virus. Polyoma virus which has been reported as occurring commonly in mouse colonies is not identical with MSV for a number of reasons, for example, much more rapid tumour induction with MSV; absence of salivary gland tumours with MSV; viraemia in mice infected with MSV but not with polyoma; inactivation of MSV with ether or heating at 56° C (polyoma resists both). Salaman and Flocks have attempted to isolate a leukaemogenic virus from urethane-induced leukaemia in mice; they conclude that the agent belongs to a type isolated in many laboratories from a variety of strains of mice and that its action is probably on haemopoietic stem cells of varying state of differentiation giving rise to erythroleukaemias of various types.

At the Mount Vernon Hospital a group of workers studying the cytogenetics of cancer state that "the clearest evidence for clonal development is the presence of the same marker chromosome in many cells; similarities in an analysis of 23 malignant tumours . . . suggest that all the cells have been derived from a single chromosomally altered cell. . . . Data on DNA content and sex chromatin, taken together with chromosome findings, support the hypothesis that human malignant tumours usually arise from one cell (or perhaps in some instances from two or some other small number of cells) in which chromosome changes have occurred". At the same centre, Powell has used propiolactone to induce malignancy in rat embryo lung cultures *in vitro*; the malignant changes were morphological and behavioural only, for when the cultures were inoculated *in vivo*, no tumours resulted even after six months, which makes the use of the term 'malignant' in this connexion somewhat dubious.

At the Hospital for Sick Children, Great Ormond Street, London, an attempt is being made to grow childhood tumours in neonatally thymectomized mice; this procedure destroys the antigenic mechanisms, but the only success was with a human embryonic sarcoma. At the same laboratory, chromosome studies of untreated neuroblastoma showed that 60 cells out of a total of 76 examined contained fragments or double minutes. In a series of nephroblastomata ranging from undifferentiated (primitive blastoma) to partially differentiated (tubular, mesenchymal and papillary type) the chromosome number suggested that the more differentiated tumours were associated with a higher chromosome number.

At the Cambridge centre the possibility of antigen liberation from tumours is the subject of experiments where a liquid nitrogen probe is inserted in the tumour in the hope of destroying part of it and liberating antigens without denaturing the proteins.

At the Strangeways Laboratory, Daniel and collaborators investigated the loss of antigen which occurs when cells are cultured *in vitro*; primary cultures from skin and lungs of human embryos were found to contain antigens of the *A* and *B* group, but already at the second sub-culture some antigens were missing and subsequent cultures consisted of a mixed population of cells some of which were strongly antigen-positive and others antigen-negative.

At Nottingham, Baldwin and associates in an extensive series of experiments on tumour immunity find that: "These studies show that DMBA-induced liver tumours possess specific tumour antigens, but they appear to be much weaker than those demonstrated in 3-methylcholanthrene-induced sarcomata (Baldwin, 1955). Although further evidence is required, the results so far indicate the absence of any strong cross-antigenicities between liver tumours. These findings contrast with the demonstration by immuno-diffusion studies (1963 Report) of common microsomal and cell-sap antigens". While tumour-specific antigens can be demonstrated in carcinogen- and viral-induced tumours in mice, and to a lesser extent in rats, little success has been achieved in experiments on spontaneous tumours. Baldwin finds that by ligation of the spontaneous tumour and thereby its disintegration, sufficient antigens are liberated to protect against a challenge with $1{\cdot}5 \times 10^6$ tumour cells; the failure of heavily irradiated tumour grafts to induce immunity may be due to sensitivity of tumour antigen to γ-irradiation.

Dawson in Newcastle finds that inoculation of neonatal rats with spleen from mice infected with Friend virus gives rise to lymphatic leukaemia; the thymus and involved lymph nodes show complete loss of normal differentiation between cortex and medulla; masses of lymphocytes infiltrate the sinuses of the red pulp of the spleen, the portal tracts of the liver, the sternal marrow and the spinal cord. In the reverse experiment (inoculation of mice with cells from rats) the cell-free filtrate from spleen and thymus of these rats gave rise to lymphatic leukaemia but not Friend disease, suggesting that the filter-passing agent causing leukaemia in rats is different from mouse Friend virus although it arises by infection with this virus.

Stuart-Harris and collaborators at Sheffield have induced anaplastic-celled tumours, subcutaneous or intrathoracic, by inoculating suckling hamsters with human adenovirus carried in tissue culture of human amnion or embryo cells and originating in aseptic meningitis in a child.

At Edinburgh, Carter *et al.* have been studing osteopetrosis virus infection in the fowl; this virus proliferates in the kidney, muscle and other tissues and causes characteristic bone lesions. In co-operation with the British Museum (Natural History), an examination of a dinosaur fossil bone (70 million years old) shows very similar lesions to contemporary osteopetrosis gallinarum, where tumours appearing in the muscles can be transplanted. At the same centre it was found that injection of cells from a minced 10-day chick embryo gave rise to an unusual sarcoma different from other transmissible tumours in the laboratory, but eighteen subsequent embryos from the same hen failed to produce further tumours.

Leslie *et al.* in Belfast have continued their study of tissue cultures of DMBA-induced rat mammary tumours; at first both epithelial and fibroblastic cell types are present, but the colonies of epithelial cells finally disappear, leaving cultures of fibroblastic cells which have little cell-adhesion and easily give suspensions of single cells. Schild and Dale at University College, London, in studies of tumour antigens find that antigenic material in the serum of tumour-bearing animals is absent in the sera of normal rats and mice, but note that the difference could be either due to the presence of a tumour-specific antigen or that the tumours used were genetically different from the host animal, and that antigenic substances could be produced or released merely because of the presence of rapidly proliferating tissue; anaphylactic tests suggest that the antigen was not tumour-specific.

Stoker *et al.* at Glasgow, in an investigation on neoplastic transformation by DNA-containing viruses, find that early-passage baby hamster kidney-cell cultures when transformed by polyoma virus increase their transplantation efficiency by a factor of 10^4; a new virus-specific cell antigen is demonstrable by rejection of transplanted transformed cells in virus-immunized animals, or by treatment with irradiated and lyophilized transformed cells. Thomsett and Allison at the same centre have found evidence that canine dermal papillomatosis and the oral variety are due to two different viruses and that, while the dermal form has not been transmitted in their experiments, the oral condition is reproducible in puppies.

Weipers *et al.* have successfully transmitted leukaemia in the cat by virus particles which are very similar to mouse leukaemia virus, and the particles can be grown *in vitro* and can be found in electron-micrographs. Weipers refers to reports from European countries that lymphosarcoma in cattle has attained enzootic proportions (Denmark has slaughtered 20,000 cattle in a control programme); in Scotland the morbidity is 250 per million cattle slaughtered.

Woodruff in Edinburgh, using a mouse mammary carcinoma growing in a hybrid strain (*A* × *CBA*), finds that the tumour is inhibited by intravenous injection of spleen cells from *CBA* mice immunized against the tumour; experiments are in progress using thoracic-duct lymphocytes instead of spleen cells and also methylcholanthrene-induced sarcoma (instead of mammary carcinoma) which possesses strong tumour-specific antigens. Woodruff does not state whether the mammary tumour was spontaneous or carcinogen-induced (the former type, unfortunately, is lacking in tumour-specific antigens).

From Ibadan comes a report by Lawson that cancer of the cervix is the commonest malignant tumour seen in Nigeria; since all males in Southern Nigeria are circumcised, some factors other than foreskin or smegma must be involved (age at circumcision is not mentioned). Oettlé in Johannesburg has been working with the kangaroo rat (*Mastomys*); this rat was at one time reputed to be the only rodent with a large incidence of spontaneous gastric carcinoma, but in recent years this incidence has receded, for it is no longer found in *Mastomys* which, however, shows a remarkable tendency to papillomatosis of the skin, perineum and vagina.

The Fahmys have continued their work on transformation versus mutation with DNA in *Drosophila*; in an experiment where seven eye colour mutants were found, the DNA was given to the fathers of the mutant flies although the mutations occurred in the maternal *X*-chromosomes.

Whisson and Connors find that aniline mustard is lethal to a mouse plasma-cell tumour but causes no regression in the rat Walker tumour (possibly the difference in efficiency depends on the state of aggregation of the cells in the two tumours).

Koller and associates, in cytogenetical investigations of neoplastic cells and leukaemogenesis, conclude that in neoplastic tissues from primary leukaemias "no correlation was found between the degree of malignancy, mitotic rate and abnormal chromosome constitution".

At St. George's Hospital, a study is being made of cytogenetics and the assessment of marrow dyscrasia: "With the cardinal exception of chronic granulocytic leukaemia, chromosome morphology in the myeloproliferative syndromes has shown no characteristic or consistent deviation from the normal pattern sufficient to merit separate categorization. The presence of a supernumerary *C* chromosome (6–12) has been noted in a variety of marrow leukaemias (Hungerford and Nowell, 1962) and in leukaemia associated with mongolism (Warkang *et al.*, 1963): in our experience the appearance of this feature bears no relation to any current haematological classification. Many different examples of chromosome aberration, both in number and in morphology, have been described since Ford, Jacobs and Lajtha (1958) first reported an abnormal pattern in 'blastcell' leukaemia. Since not all forms of this and allied marrow diseases show morphological chromosome change, it is tempting to speculate on an association between those that do so; but this would imply a capacity to distinguish between cause and effect which we do not yet possess".

The most arresting development in biochemistry, that dealing with DNA, RNA and *m*-RNA, has been the subject of a number of investigations in cancer; the current ideas in this field are very difficult for outsiders to grasp properly; for example, Kemp at St. George's, in discussing the effects of actinomycin *D* (AMD) on human chromosomes, says: "AMD is known to bind to the guanine moiety of DNA and thereby inhibit DNA-dependent RNA synthesis, possibly by interfering with the pathway and function of the DNA-dependent RNA polymerase operating in the minor groove of the DNA molecule (Reich, 1964). While it is known that AMD binds to those regions of the DNA molecule actively engaged in RNA synthesis, it is not known whether it also binds to the genetically repressed regions of the DNA. If, as has been suggested, this repression results from the close association of the DNA with other molecules, such as histones, it would seem quite possible that the binding of AMD to such repressed DNA would be prevented. Further, if the sites of binding of AMD to the chromosomal DNA could be detected, it would be possible to map the genetically active regions along the chromosome and to compare these regions in differentiated cells with different functions and in malignant cells and their normal counterparts". Elek *et al.* at the same centre have studied the nature of attachment of antibody molecules to infective particles of polyoma virus using electron microscopy and negative staining of flagellar fragments; electron micrographs indicate that the antibody molecules carry the specific sites at the ends of their long axis. The molecule of antibody thus becomes attached to a cylindrical antigen radially surrounding the antigen like the bristles of a

bottle brush. This orientation suggested that the antibody is inserted into the surface of a flagellum in a manner that is directionally fixed, presumably by surrounding molecules. This type of coating provides a physical explanation of the inhibition of the infectivity of viruses in the presence of antibody. At present, experiments are in progress to study the transformation of hamster kidney cells by polyoma virus in a quantitative manner, and in particular in relation to the phase of cell division.

Amoroso and Stein-Werblowsky at the Royal Veterinary College, London, find the semen of boars, bulls and to some extent humans inhibitory for the growth of transplantable tumours in the rat and mouse; the active factors appear to be the phospholipids in the semen.

Currie and associates at Aberdeen have studied the growth and regression of DMBA-induced mammary tumours in rats treated by oral or intravenous administration; 80 per cent of the mammary tumours regress when the ovarian hormones are removed by ovariectomy (the latest techniques were used in this work, tritium-labelled thymidine, electron microscopy, enzyme studies and neonatal thymectomy).

Foulds, in a theoretical discussion of genetic action in normal and neoplastic development, introduces a new terminology—total genome, effective genome and facultative genome, and the neoplastic expression of the effective genome is via "selection, transcription and translation of the RNA transcript in the synthesis of a specific protein".

Radiotherapeutics and Radiobiology

Radiation has been shown in many instances to be a cause of cancer and leukaemia in man, although, in general, the doses that have been received by the irradiated populations were large. The Oxford Survey of childhood cancers, under the direction of Alice Stewart, first revealed that malignant disease can be produced *in utero* by doses of the order of 10 r., and the latent period for leukaemogenesis under these conditions has now been shown to be 4–5 years and this is substantially shorter than is required for the induction of leukaemia in adults. The possibility that radiation may play a part in lung cancer associated with smoking has frequently been considered since the high incidence of this disease among the early uranium miners was believed to be an example of radiation carcinogenesis. So far, however, no evidence for such a hypothesis has been found. Radiation-emitting particles of natural origin are continually inhaled and the lung is the organ most heavily exposed to normal environmental radiation. The finding in New Zealand that cigarettes contained minute quantities of polonium led to the post-mortem measurement of polonium in different organs of smokers and non-smokers. Though the lungs of the former contained three times as much polonium as those in non-smokers, there is no evidence that this is a causal factor nor that the increase is due to the polonium content of the cigarettes. Damage to lungs by smoking may lead to impairment of the normal physiological processes which keep the lungs clean. In Glasgow the natural radiation burden of the lungs of mice is being greatly reduced by maintaining the animals in an atmosphere free from radon, but this does not appear to have abolished the appearance of lung adenoma. A paradoxical finding is that the induction of lung cancers by high doses of radiation only is increased if they are irradiated in atmospheres of nitrogen instead of in air. This is the exact opposite to cell killing or mutation induction, in which anoxia protects against radiation damage.

The complexities of radiation carcinogenesis are illustrated for thyroid carcinoma which has been induced with radioactive iodine in man and in experimental animals. Donniach and his colleagues showed that if the radionucleotide is given to rats at birth the production of thyrotrophic hormone by the pituitary is stimulated and that this is involved in the eventual appearance of tumours.

Accurate dosimetry continues to present problems, especially in connexion with some of the newer very-high-voltage equipment which is now coming into clinical use. A considerable amount of research effort is being devoted —chiefly by the physics departments of the major teaching hospitals—to these and other technical problems and several ingenious new methods have been devised. The use of computers for treatment planning is being tried out at the Medical Automation Centre of University College Hospital, and plans are being made to have a direct *telex* link between the centre and the hospitals. A great deal of clinical research is being devoted to the problems of irradiation under high-pressure oxygen. Radiobiological considerations indicated many years ago that local clearance of large tumours ought to be facilitated by irradiation under high pressures of oxygen, but as yet it is not clear what the benefits are in practice. Good commercial equipment for treatment under hyperbaric oxygen has now been installed at several centres and carefully controlled clinical trials should show within a few years the degree of usefulness of this procedure.

Much experimental work is being devoted to the search for radiosensitizers; if such substances are to find application in practice, then they must show selective action for tumour tissue since the maximum dose that can be given is determined by normal tissue tolerance, and if this is sensitized to the same extent as the tumour no advantage is gained. The radiotherapist is equally concerned with the response of the surrounding tissue as with that of the tumour; yet, until recently, there has been little quantitative experimental work in the relationships between dose and the fraction of cells killed in normal tissues, and most of the information on the radiation response of cells was obtained with tumour cells. This situation is now being remedied; Withers has developed a method for measuring the dose-response curve for skin cells in mice; workers at Guy's and Westminster Hospital are making quantitative studies on the effects of radiation on bone growth, and Denham is investigating the relationship between sensitivity to X-irradiation and metabolism and growth cycle for the developing rat retina. The radiosensitivity of the mouse ovary has been found to depend critically on age, the D_0 being 290 r. at one day of age, falling to 16·5 r. at one week and rising again to 54 rads at one month (St. Bartholomew's Hospital). The radiosensitivity of erythropoietic stem cells in the mouse was found at the Christie Hospital to depend on the level of erythropoietin. From all this work it is very clear that the radiosensitivity of normal tissue is very variable and is influenced by many factors which are not yet understood. A key parameter in determining the fractionation schedule for radiotherapy is the recovery of normal tissue in the intervals between irradiations, and Lamerton and his colleagues have shown remarkable differences in this respect between different organs. Jolles has observed profound changes in connective tissue and believes that circulating factors which increase capillary permeability are released on exposure to X-rays. Both he and the late Dr. Wilson noted that radiation alters the behaviour and turnover rate of the mucopolysaccharides in extracellular tissue. The implications of such changes for radiotherapy remain to be elucidated.

Another line of investigation which emphasizes that radiotherapy cannot be understood—or improved—by concentrating on the tumour cells alone, and that the complex interplay with the host has to be taken into account, is provided by a comparison of the radiosensitivity of cells cultured from different tumours *in vitro* and the response of the tumour *in vivo*. Thus, cells from a fibrosarcoma induced with a plastic film were found to be sensitive to X-rays *in vitro*, while on injection into syngeneic rats they give tumours which are very radioresistant. For a series of primary chemically induced

fibrosarcomata induced in rats it was shown that the host environment exerts a predominant influence on radiosensitivity (Dawson, Field and Madoc-Jones). An observation made at the Chester Beatty Research Institute points to the possibility that radiosensitization with compounds having radiobiological properties similar to desoxybromouridine (BUDR) may be of practical value. BUDR is known to be incorporated into the DNA of dividing cells and this resulted in such cells being more sensitive to X-rays. In a series of leukaemia cells having different radiosensitivities in tissue culture it was found that incorporation of BUDR sensitized the radio-resistant cells to a greater extent than the more radiosensitive cell lines. The differences in radiosensitivity of these cells arise out of differences in their capacity to restore radiation-induced lesions, and BUDR appears to sensitize by interfering with post-irradiation repair processes. BUDR exerts its greatest effect on those cells which have the greatest repair capacity and in this way may provide useful differential radiosensitization.

Clinicopathology of Cancer

Tumours arising from human trophoblast are rare, and incidentally are examples of a tumour arising in the foetus which infiltrates the mother. From Charing Cross Hospital comes a report of forty-four patients with trophoblastic tumours, thirty-nine of them with overt metastatic disease, who were treated with a combination of methotrexate and 6-mercaptopurine during a 6½-year period. Only six patients died, and the remainder are in complete remission as shown by clinical, radiological and hormonal evidence. Six patients had successful pregnancies after chemotherapy, and the infants were normal. Chemotherapy of trophoblastic tumours is now established as a triumph of modern medicine over what was once a fatal disease.

The University of Glasgow Veterinary School continues its researches on lymphosarcoma in domestic animals and includes in its study the curious lymphosarcoma-like, transmissible venereal tumour of dogs. It will be recalled that this was the first tumour (or tumour-like condition—there is no real distinction) shown to be transplantable. No microbiological agent has been demonstrated as a causative factor, transmission depending on the inoculation of viable tumour cells. The disease is almost extinct in England but is common in some parts of the world, East Africa and Japan, for example. The tumour is said to have only two-thirds of the normal chromosome complement. An attempt is still being made to isolate a virus from it.

It is apparent that the concentration of patients and the specialist knowledge available in the few large institutions devoted to the management of cancer is good for both specialist and patient. It is a fact, however, that 'cancer' is not recognized as a speciality in the National Health Service, though one form of cancer therapy, that is, irradiation, is so regarded. Pooling of material for clinical research has the disadvantage that some clinicians must sacrifice familiarity with the conditions selected for study, but this is offset by the rapidity with which unsuspected data may come to light and the adequate testing of new therapeutic measures be carried out. One notes with approval the setting up of a Thymic Tumour Panel; thymic tumours are rare, and so far only in the United States has there been any opportunity of examining a large series of cases. The publication of the researches of the Testicular Tumour Panel has been conspicuously successful.

The early detection of cancer is still a major topic. St. Mark's Hospital reports that only a little more than 3 per cent of all rectal cases seen were at an 'early' stage of development. In a study of early cases no evidence was found over the past 40 years that patients are coming earlier for treatment. With a mounting campaign for the setting up of centres for the early detection of cervical carcinoma in well women, reports from a number of centres corroborate the established value of the present cytological procedure. The final report from Way of the North of England Council states that, between 1947 and 1963, 476 cases of occult cervical carcinoma were discovered and treated, some of the patients later having successful pregnancies. During this same period 2,094 clinical cancers were treated. In 1964 the number of preclinical cancers detected by cytology exceeded the numbers detected by clinical methods for the first time ever. In contrast with this gratifying state of affairs it is fair to say that there are still no comparable methods for the detection of early visceral malignancy nor for the early mammary carcinoma. The value of the prophylactic surgery for preclinical cervical carcinoma will only be confirmed when the death rate from cervical carcinoma is seen to fall.

At University College Hospital, Ross and Marshall-Jones have studied the metabolic disturbances associated with carcinoma of the bronchus. These patients with bronchial carcinoma developed bilateral adrenal hyperplasia with extremely high levels of blood and urine corticosteroids, not elevated by corticotrophin nor depressed by dexamethazone. Two of these showed hyperkalaemic acidosis due to corticotrophin production by the tumour. Another two exhibited dilutional hyponatraemia due to the production of antidiuretic hormone by the tumour, one of them having severe myasthenic neuropathy. Urich, Dayan and Montgomery summarize their published observations on the obscure and uncommon neuromyopathy, the result of bronchial and other carcinomas. Both these reports underline the potentially rich field of investigation which lies in the oblique approach to tumours by studying their effects or concomitants, and again emphasize the advantages to be gained from co-operation among specialists.

OBITUARIES

Dr. F. J. Wilkins

Dr. F. J. Wilkins, a director of Glaxo Group, Ltd., was killed in the early hours of the morning of October 27, 1965, at London Airport as the result of the crash of a Vanguard aircraft on a flight from Edinburgh to London. The original flight, timed to leave Edinburgh at 5.30 p.m. on October 26, had been cancelled owing to fluctuating fog in London. When another flight became available at a very late hour, Fred Wilkins was one of those who decided to take it instead of travelling by train or remaining in Edinburgh overnight. This decision was entirely characteristic of him, and it was a product of the restless energy which led him to achievements denied to many of his contemporaries who had seemed likely to surpass him when they were younger.

Wilkins was born in Cardiff in 1905, and he obtained all his early education in that city. After obtaining a London B.Sc. degree and a Diploma in Industrial Chemistry in 1924, he decided to engage in research at Cardiff Technical College, and he spent the next three years on investigations relating to nitrosyl sulphuric acid and to the catalysed oxidation of ammonia. For this work he was

awarded a London M.Sc. degree. He then decided to pursue reaction kinetics in greater depth than was possible at Cardiff. To this end, and with the help of a research grant from the British Non-Ferrous Metals Research Association, he joined the Department of Physical Chemistry in the University of Cambridge, where he worked on a number of topics under the direction of E. K. Rideal. The most important of the subjects he studied were the oxidation of copper, and, as an offshoot, the oxidation of hydrogen with copper as the catalyst. He showed that the oxidation of copper could be considered as the sum of four consecutive processes, while the reduction of cuprous oxide by hydrogen consisted of six consecutive reactions. In all, he published, either as sole or as joint author, some six papers and two short notes while he was at Cambridge, and he received a Ph.D. degree in 1927.

In 1930 he obtained a Department of Scientific and Industrial Research senior research award and he moved to University College, London, where F. G. Donnan was the professor of physical chemistry. There Wilkins worked on gaseous adsorption, and he published one paper on the effect of intensive drying on the accommodation coefficient of liquid and solid surfaces for molecules of their own vapours. However, in spite of the fact that his main work allowed him plenty of time to indulge his tastes for music and the visual arts, Wilkins gradually found himself becoming less interested in an academic life, and in 1933 he joined the nitrates and sulphuric acid group in the Billingham Division of Imperial Chemical Industries, Ltd.

The problems and environment there were much to his liking, and he threw himself with great energy into improving the efficiency of the plants. After three very successful years as a plant manager, he moved first into the research department and then into the technical department, in the latter of which, during the first two years of the war, he was in charge of the start-up and proving trials of a number of ammonium nitrate explosive factories.

In 1941, C. S. Robinson, who had been managing director at Billingham and who had been seconded to the Ministry of Supply as director-general of the Royal Ordnance Filling Factories, was faced with the task of expanding the Royal Ordnance Factory organization in order to meet the constantly changing demands of the Services, and he managed to extract a number of 'bright boys', Wilkins among them, from Billingham. Wilkins was located at Bridgend, which was the headquarters of the western regional filling factories of Bridgend, Glascoed and Hereford, and he created and managed a highly efficient development team. Among their achievements were substantial improvements in the operation of a fully mechanized detonator filling plant and of a continuous 25-pounder shell filling plant. The risks involved in these processes were substantially reduced, and both productivity and quality were much improved.

At the end of the war, Wilkins decided to leave Imperial Chemical Industries and stay in Government service, and he became, first, director of chemical research and development, and, later, principal director of scientific research (defence). However, after some time he found that the task of being a head-office administrator was not an entirely satisfactory one, and in 1949 he accepted an invitation to become a local director of Glaxo Laboratories, Ltd., in charge of their northern factories.

All his work up to that time had been connected with well-known inorganic chemical processes involving the same types of reactions as those which he had first studied in 1924. The complex organic chemistry of the corticosteroids and the production of antibiotics by fermentation were new fields of endeavour to him, and they presented him with a major challenge, a situation which always brought out his best qualities. But he did not confine his interests to purely technical matters, and he became intensely interested in labour relations and in the training and proper utilization of graduate staff. Because of the new ideas which he introduced and his forceful personality, his influence throughout the Glaxo organization spread well beyond the realms of his own bailiwick, and in 1956 he joined the main board of the company as deputy managing director. In 1961, when the Glaxo organization was remodelled in the form of a holding company, Glaxo Group, Ltd., and of a number of operating subsidiaries, he was made chairman and managing director of Glaxo Laboratories, Ltd., the largest of the subsidiaries in Britain, as well as being made a member of the board of the Group. Under his direction, Glaxo Laboratories, Ltd., continued to expand and flourish, in spite of some slowing down of innovation in the pharmaceutical industry of Britain as a whole.

Fred Wilkins's interests were extremely wide, and he even found time to go in for farming on quite a large scale, employing always, of course, the most up-to-date methods. He travelled widely on the Continent and in North America, and he made many friends whom he and his wife were fond of entertaining at their home in Burnham Beeches.

Although Wilkins made a very considerable contribution to all the organizations in which he worked, his influence on Glaxo Laboratories was much the most profound. His outlook was partly that of a scientist with a highly analytical mind, and partly that of an artist, for he took a great delight in music, in ballet and in the art of the High Renaissance. He was never at a loss for a new idea, and he was always anxious to give the younger members of the staff the best possible chance of proving themselves. He was warm-hearted and volatile, and, as he liked saying, a true Welshman. For him, technological innovation and artistic creativity were the two aspects of human endeavour which were most worth while.

A. H. Wilson

Prof. Mary Barber

The sudden death of Prof. Mary Barber on September 11, 1965, is an irreparable loss to bacteriology.

Mary Barber was born in 1911. Her father, Dr. Hugh Barber, is a distinguished physician who trained at Guy's Hospital, became a Fellow of the Royal College of Physicians in 1933 and has practised medicine for many years in Derby. She obtained the M.R.C.S., L.R.C.P. qualification from the Royal Free Hospital in 1934, and the M.B., B.S. (London) in 1936. Between 1934 and 1937 she held the posts of house physician, clinical assistant to out-patients, resident pathologist and A. M. Bird Scholar in pathology at the Royal Free Hospital. In 1958 she went to the Archway Group Laboratory in Highgate and in 1940 became assistant in the Department of Pathology at the Postgraduate Medical School of London. She took the London M.D. in pathology in 1940. In 1947 she was appointed lecturer in bacteriology at the Postgraduate Medical School and in 1948 became reader in bacteriology at St. Thomas's Hospital Medical School. While holding this post she spent a few months at the Institut Pasteur in Paris during 1950–51. She stayed at St. Thomas's until 1957, when she returned to the Postgraduate Medical School, this time as reader in clinical bacteriology. In 1964 the title of Professor of Clinical Bacteriology was conferred on her by the University of London.

Mary Barber will always be remembered for her work on hospital infections, particularly those caused by staphylococci: but it should be emphasized that this work in which she established her unique reputation was broadly based on a sound general knowledge of clinical bacteriology and pathology. In her early work she was interested in listerella and erysipelothrix infections, in puerperal sepsis and in the antibacterial activity of 2-aminophenol and some simple derivatives. Later she became increasingly absorbed in the staphylococci and very soon became an authority on almost every aspect of the challenge they present. A clinical bacteriologist by training and ex-

perience, she had a wide knowledge of the clinical and epidemiological effects of staphylococcal infection; when penicillin and other antibiotics became available she was quick to appreciate the great opportunities and the dangers created by their use. She was able to give sound advice to clinicians on the proper use of antibiotics, but without attempting to usurp the responsibility of the physician for the care of patients. She was one of the first to point out the dangers of the development of drug-resistant strains of staphylococci and other bacteria, and saw very clearly that the only rational way to meet this threat was to have a rational policy for the use and, if necessary, the restriction of antibiotics and for the control of cross-infection.

But Mary Barber was more than a clinical bacteriologist. She was intensely interested in bacteriology or microbiology for its own sake, as a branch of biology. She was always experimenting with different laboratory methods for demonstrating the behaviour of staphylococci in laboratory media, and particularly for detecting the penicillinase-producing strains which have become so prevalent in hospitals in almost all parts of the world—though she had great faith in the well-tried and simple method of the ditch plate, a fact familiar to all who heard her give papers at meetings or read her published works. Besides her technical skill as a bacteriologist, she had also a wide knowledge of microbiology, of microbial chemistry, microbial genetics and of the relation of structure to function in antibiotics and chemotherapeutic drugs. Although in these fields she never claimed expert and detailed knowledge, her mastery of the principles, her ability to see the wood for the trees, and even at times her command of detail were remarkable. The semi-synthetic penicillins with their new range of antibacterial activity presented an exciting challenge which she was quick to take up, since it brought together so many different facets of microbiology.

As a speaker she was always interesting and stimulating, often humorous and provocative, never dull. As a person she was unique. Essentially friendly, sociable and humane, she had no use for pomp or pretentiousness. But she was forceful and outspoken in attacking attitudes of mind with which she did not agree, and in defending causes in which she believed. The world of bacteriology, and indeed the bacteriology of the world, has lost far too soon one of its most active and stimulating workers. R. Knox

NEWS and VIEWS

Metallurgy in the University of Cambridge : Prof. R. W. K. Honeycombe

Prof. R. W. K. Honeycombe, whose election to the Goldsmiths' chair of metallurgy in the University of Cambridge was announced recently, was born and educated in Australia. He studied metallurgy in the University of Melbourne under Prof. J. Neill Greenwood. As a research officer in the lubricants and bearings section of the C.S.I.R.O. from 1942 to 1947, he worked on bearing metals and plastic deformation under Dr. F. P. Bowden. His collaboration with Dr. W. Boas during this period led to an appreciation of the role of the anisotropy in the plastic deformation of non-cubic metals when they are thermally cycled. In the Cavendish Laboratory from 1948 until 1951, first as I.C.I. Fellow, and then as a Royal Society Armourers' and Braziers' Fellow, Honeycombe's principal work was concerned with the deformation of single crystals. On his appointment as senior lecturer in physical metallurgy in the University of Sheffield in 1951, he became deeply involved in teaching as well as research and played a prominent part in developing postgraduate courses. In 1955 he was appointed to the chair of physical metallurgy. At Sheffield he has conducted researches into the deformation of alloys and into tempering, intergranular brittleness and precipitation hardening in alloy steels. He holds a substantial Science Research Council research grant in support of his work on alloy steels. Prof. Honeycombe has received the Rosenhain Medal and the Sir George Beilby Medal and Premium; he was awarded a D.Sc. by the University of Melbourne in 1961 and he has held visiting professorships in that University and in Stanford University. He has taken an active part in the life of the University of Sheffield, has served as Dean of the Faculty of Metallurgy and has been a member of the small Senate Committee charged with planning future academic developments in the University. Prof. Honeycombe succeeds Prof. A. H. Cottrell, who has been appointed deputy chief scientific adviser, Ministry of Defence (*Nature*, 208, 19; 1965).

U.S. National Bureau of Standards : Samuel Wesley Stratton Award

Dr. Harry Allen, deputy director of the Institute for Materials Research, and Dr. Deane B. Judd, assistant chief of the Metrology Division, have received the 1965 Samuel Wesley Stratton Award of the National Bureau of Standards, U.S. Department of Commerce. The Award is given each year to recognize outstanding scientific or engineering achievements by a member of the staff of the Bureau. Dr. Allen was cited for "distinguished research contributions to infrared and quadrupole spectra of molecules and for leadership in advancing high resolution analysis of asymmetrical molecular tops". Dr. Allen was chief of the Analytical and Inorganic Chemistry Divisions and of the Inorganic Materials Division of the Bureau before being appointed to his present position in 1965. Dr. Judd's award was for "major basic contributions to the science of color measurement and color vision and the development of color standard for business, science and industry". Dr. Judd has worked in the National Bureau of Standards for 38 years on problems ranging from standards for colour measurement to camouflage and colour blindness.

U.S. National Bureau of Standards : Dr. R. C. Casella

Dr. Russell C. Casella has joined the U.S. National Bureau of Standards as a theoretical physicist in the Solid State Physics Group of the Institute for Materials Research. An expert in the theory of solids, he will be investigating the problem of penetration depths in the superconducting, heavily doped semiconductor, $SrTiO_3$. Dr. Casella has conducted investigations into the symmetry of electronic band structures, optical and superconducting properties of solids, and elementary-particle physics at the Watson Research Center of International Business Machines. From 1952 until 1958 he was a graduate student and research associate at the University of Illinois. He has also worked at the Air Force Research Center at Cambridge, Massachusetts. Dr. Casella was born in Framingham, Massachusetts, and received his B.S. from the Massachusetts Institute of Technology in 1951 and his Ph.D. from the University of Illinois in 1956. He is a member of the American Physical Society.

Sir Arthur Keith (1866–1955)

Among this year's centenaries of note is that of the birth, on February 5, of Arthur Keith, of Aberdeen.

Having gained his initial education in that city, Keith studied medicine in London and Leipzig, eventually becoming professor at the Royal College of Surgeons. As a noted research worker in anatomy and embryology, Keith was elected a Fellow of the Royal Society in 1913, and 4 years later he was appointed to the Fullerian chair at the Royal Institution. He was well known for his work on the development of early man and was an authority on fossil man. Keith wrote some attractive books, among them being *Human Embryology and Morphology* (1901), *Ancient Types of Man, Antiquity of Man* and *A New Theory of Evolution*, published in 1948. His presidential address to the British Association for the Advancement of Science in 1927 was an outstanding revision of the Darwinian theory. Despite his wide field of activities, Keith remained a staunch Aberdonian at heart, so that it is not surprising that he was Rector of Aberdeen from 1930 until 1933.

New Variable Energy Cyclotron at Harwell

THE first stages of commissioning a new variable energy cyclotron have been carried out successfully and rapidly at the Atomic Energy Research Establishment, Harwell. Within 24 h of switching on the machine, the beam was accelerated to the full radius. The difficult task of extracting the beam for experimental use has yet to come and the immediate programme is designed to explore the behaviour of the machine and to gain experience with it under various operating conditions. The cyclotron, with its buildings, research and development, will cost £1,650,000; it is to be initially used for studies of radiation damage, radiation chemistry and radiochemistry. The accelerator is a 70-in. spiral-ridge cyclotron designed to accelerate ions of up to about mass 40. The design provides for an internal beam of up to 1 m.amp. of 50-MeV protons (ultimately up to 100 m.amp. externally) and microampere beams of heavy ions, with energies in some cases up to 10 MeV per nucleon. A beam of 22·7-MeV ions was initially accelerated to the full extraction radius while the beam current was deliberately restricted to 2 μamp. Energies of as high as 50 MeV have since been achieved with currents of 20 m.amp. There are nine positions in which samples may be irradiated, one of which is on a probe in the internal beam. The external beam may strike a target in the cyclotron vault or be deflected by a bending magnet to any one of seven positions in three separate target rooms adjacent to the vault. The target rooms are shielded from one another and from the main vault so that experiments can be set up in one while irradiation proceeds in another. During operations the machine and targets can be observed from the control room through a water-filled window or by closed-circuit television.

Ex Opera et Industria

THE presidential address to the Institution of Mechanical Engineers at their meeting on October 27, 1965, was given by H. N. G. Allen, deputy chairman and joint managing director, W. H. Allen, Sons and Co., Ltd., Bedford, and was entitled *Ex Opera et Industria*, a tribute to the Allen family motto, signifying (with implied overtones) 'by service freely given and by diligent application'. This tribute, which constituted the first part of the address, was an appreciation of the life-work of two eminent engineers, the late W. H. Allen, who took over a small jobbing company, Newberry and Co., Cardiff, in 1865, thus founding the firm of W. H. Allen, and his eldest son, the late Sir Richard Allen. This first part is essentially historical, covering the years 1865–1955; but it sets the stage for what was, perhaps, the more important motive of this discourse, the second part, which considers "Unity of Purpose: Reflections and Queries". It is argued that in a rapidly changing world it may be questioned whether everyone concerned really understands what is meant by engineering, both in its own right and also as one vital organ of the complex living system which makes up a balanced industrial enterprise, and what kinds of engineer and engineering will be required in the future in industry. The answer to these and other pertinent questions raised by the president would appear to lie with the initiative for engineering co-ordination being within the province of the Council of Engineering Institutions, recently granted its Royal Charter. Mr. Allen's plea is for pooling of ideas to get these actions moving. Reappraisal of the term 'engineering' in depth, breadth and context is required, and implicit in this is the conception, creation or utilization of an engineering product. Next, investigation of the different kinds of engineering required and of the relationship of engineers and engineering technicians is needed along with re-examination of educational and training requirements; finally, to present a unified front to schools on the meaning of engineering, career patterns available, and to consider educational and training programmes to this end. "If Science is knowledge and Engineering is applied knowledge, surely Wisdom is knowing how and when to apply that knowledge." The title of this address is one which Mr. Allen thinks might well be adopted by all engineers. His remarks must have given his audience much to think about and will doubtless lead to healthy repercussions throughout the professions and industry. The address is in the course of publication by the Institution of Mechanical Engineers.

Scientific Research in Schools

THE *Report to Council, 1965*, of the Scientific Research in Schools Committee of the Royal Society has recently been published (Pp. 18. London: The Royal Society, 1965). The scheme, under which a committee of the Royal Society gives assistance to teachers of science to carry out research, has been in existence for 8 years. One hundred and seventeen teachers are now working under it, each being advised by a designated expert, and their investigations extend into ten major branches of science. Over the past year, £5,472 was expended in giving financial assistance to teachers, the strain on the Royal Society's own resources being in part relieved through contributions from eleven companies and the United Kingdom Atomic Energy Authority. In the opinion of the Royal Society, there is scope for further extension of the scheme, which is looked on favourably by head teachers and deserves to be more widely known.

South Australian Museum

The Records of the South Australian Museum includes an obituary and bibliography of the late Dr. H. M. Hale, director of the Museum from 1931 until 1960 (15, No. 1; 1965). Other articles include a revision of the Australian and New Guinea Dromini, Aboriginal rock poundings on Gallery Hill, North-western Australia, and new species of *Holachila* from Victoria and southern New South Wales. It is interesting to note that the rock poundings are the result of battering the surface of the rock with a rounded stone until the dark-coloured patina is destroyed, leaving a white mark as the shape of the design. The *Records* maintains its high standards of scholarship, illustrations and general format.

Auckland Institute and Museum

The Records of the Auckland Institute and Museum (6, No. 2, October 15, 1965) is, as usual, well illustrated and includes three papers by Mr. W. F. Ponder on the family Eatoniellidae, a revision of a recent species previously known as *Notosetia Iredale* and the recent and fossil species of *Estea Iredale*, respectively, all from New Zealand. The final paper, by A. W. B. Powell, deals with molluscan systematics.

University Research in Canada

THE *Annual Report on Support of University Research, 1964–65*, of the National Research Council and Medical Research Council of Canada gives detailed information on the former Council's programme of support for research in science and engineering and of the research awards of the Medical Research Council (Pp. vii+271. Ottawa: National Research Council and Medical Research Council, 1965. 50 cents). Direct university support totalled 17·8 million dollars, compared with 12·85 million dollars in 1963–64; of this, 1·86 million dollars was on postgraduate scholarships, 9·27 million dollars on operating research grants to university staff, and 2·1 million dollars on major equipment grants; 1·25 million dollars went to the Atomic Energy Control Board. Indirect support to universities totalled 1·29 million dollars. Lists of recipients of awards, scholarships and fellowships are included. Of the 7 million dollars expended on the extra-mural programme of the Medical Research Council (5·16 million dollars in 1963–64), 5·18 million dollars was on research grants, 610,109 dollars on fellowships, 348,823 dollars on scholarships, and 532,427 dollars on associateships. Lists of operating grants and of major equipment grants are included.

Eskimo Administration

THE Arctic Institute of North America has recently published the third in a series of studies designed to cover the administrations of all groups of the Eskimo race other than that in Siberia. The first two studies dealt with Alaska and Canada, and the third (Arctic Institute of North America. Technical Paper No. 16: *Eskimo Administration*: 3; *Labrador*. By Diamond Jenness. Pp. 94. Montreal, Washington, D.C., and New York: Arctic Institute of North America, 1965) covers Labrador. The history of the Eskimos of the Labrador Atlantic coast begins with a tale of conflict with white settlers from the sixteenth century, when European fishermen began to appear in numbers in the southern area; this unhappy situation lasted until the late eighteenth century when two Moravian missionaries negotiated a truce between the Eskimos and the settlers to the south. It is possible that the history of contact between Europeans and the Eskimos began earlier than this, if the recent recognition of Viking settlement in Newfoundland can be related to the Icelandic saga of a peaceful meeting with "small ugly men with broad faces", who left the Vikings in peace. In any event, after two centuries of struggle, the negotiated truce allowed gradual white penetration of southern Labrador, and the Eskimos there withdrew and concentrated in Hamilton Inlet area until they were absorbed into the white population. In northern Labrador the Moravian missionaries created an amicable atmosphere through their pressureless but successful evangelistic endeavours. Contact with the external world came with the Hudson's Bay Company and Newfoundland fishermen, and the history of the Eskimos since the mid-nineteenth century has been of increasing assimilation into and emulation of European and Canadian standards of dress, economy and customs. The outstanding lesson to be learned from this period in Labrador is simply that of the unqualified success of the Moravian missions, which, through devout yet eminently practical methods, painlessly achieved for the Eskimos a respected place in Newfoundland affairs; further advances will depend on the Eskimos of northern Labrador themselves.

Advances in Oceanography

A THIRD volume of *Progress in Oceanography*, edited by Mary Sears, of Woods Hole Oceanographic Institution, for the Pergamon Press, commemorates the seventy-fifth birthday of Prof. Hans Pettersson in 1963 (Pp. xxiii+407. London and New York: Pergamon Press, 1965. 105*s*. net). It contains thirty articles by his former students and colleagues. The majority deal with the sea floor and its sediments, to which a wide range of scientific techniques have successfully been applied. The remaining contributions deal with aspects of geophysics, marine chemistry and biology. The present volume departs somewhat from the systematic review of outstanding problems which was one of the main objects of the series, but it achieves the overall purpose of keeping oceanographers, and others interested in the sea, conversant with recent research and advances over a wide field. It is an appropriate and timely reminder of Prof. Pettersson's pioneering achievements. The third volume of *Oceanography and Marine Biology*, an annual review edited by Harold Barnes for George Allen and Unwin, Ltd., appears at the same time (Pp. 421. London: George Allen and Unwin, Ltd., 1965. 84*s*. net). Two-thirds is devoted to marine biology, particularly the systematics and distribution of chaetognaths, and the endocrine physiology of polychaetes and fishes. The remainder consists of review papers on waves, the carbon-dioxide system in the sea, exchange of chemical substances between sea and air, disposal of waste and pollution of the sea, conditions for life on the abyssal sea-floor, the biology of the north-east Atlantic herring population, and on the methods of determining phosphorus in sea water. Both books tend to serve as bound scientific journals containing some description of original work as well as review articles, and will probably be most useful in filling gaps between the journals and text-books and in emphasizing the unity of environmental science.

Effect of Duration of Curing on Slag–Portland Cement Concrete

THE use in concrete of ground blast-furnace slag mixed with Portland cement has in some countries been increasing during the past decade, and in view of the incomplete concrete curing procedures commonly adopted on construction sites in South Africa, it was decided that the effects of such limited curing of Slag–Portland cement concrete should be investigated. This has been done and the results are embodied in a paper by G. J. R. van der Meulen entitled *Effect of Duration of Curing on Slag–Portland Cement Concrete* (National Building Research Institute, South African Council for Scientific and Industrial Research, Pretoria. CSIR Ref. No. *R/BOU* 158. Reprinted from *Construction in Southern Africa*, **10**, 9; January 1965). The trend of this work was to compare the compressive strengths of various slag–Portland cement concretes with similar Portland cement concretes when they were continuously wet-cured until tested and when they were allowed to dry out after one day of wet curing. The object was to reproduce the effects of the best and the worst curing which concrete is likely to undergo in building practice. The results are not without a wider significance in other countries. From the experiments carried out, it was found that the effects of inadequate curing on slag–Portland cement concrete are severely adverse. The compressive strength of slag–Portland cement concrete is more sensitive to the effects of limited curing than that of similar Portland cement concrete. "The investigations showed that in nearly all cases the strengths of dry cured slag–Portland cement concretes at three months were not as great as those of similar Portland cement concretes developed after six days under the same curing conditions". It is concluded that it is therefore important to pay special attention to adequate wet-curing of slag–Portland cement concrete, particularly if it is used in thin sections. The paper includes details of mixes used, ages at test, and comparative graphs of compressive strengths of wet- and one-day-cured specimens of slag–Portland cement and normal Portland cement concretes, and also contains a short list of references to other workers who have been concerned with similar problems.

The Names of Early Man

Several publications during the past year have provided some guidance to the nomenclature of the fossil Hominidae. Dr. K. P. Oakley's *Frameworks for Dating Fossil Man* was the first to gather together some of the plethora of names that have accumulated around the finds of early man and his immediate family. Dr. Michael Day's *Guide to Fossil Man* indicated in greater detail some of the often confusing terminology used in published discussions on the physical relationships between these finds, some of which, by their fragmentary nature, were incapable of any degree of precise definition. Most recently has appeared *The Nomenclature of the Hominidae*, by Bernard G. Campbell (Royal Anthropological Institute of Great Britain and Ireland. Occasional Paper No. 22. Pp. v+34. London: The Royal Anthropological Institute of Great Britain and Ireland, 1965. 10*s*.). In this, he presents a full list of the nomina proposed for fossil hominid finds of Pleistocene age, and a review of these which establishes that a number of the existing names are invalid on the basis of the revised edition of the *International Code of Zoological Nomenclature*. Some idea of the complexity of the problem may be gained from the fact that sixty Pleistocene specimens have been made the types of new hominid taxa; these correctly include nineteen new genera and fifty-five new species and subspecies, with forty-four names which are synonyms, and twenty-one invalid names. The result is that almost every important fossil find is a distinct named species, and clearly this must disguise the varying degrees of relationships that must have existed within the general evolution of mankind. The recent finds of fossil man from Africa, Europe and Asia combine with the old to present a quite remarkable series of specimens falling within a broad distribution in time and space, and any future finds will improbably create new species, although they may extend the known habitat of man in early or mid-Pleistocene times; the recent finds at Vértesszollös in Hungary are important in this respect. The author may have been rash in prophesying the dismissal of the ten new hominid taxa created since 1955, but without doubt his paper represents an important advance in the control of hominid nomenclature.

Guide to Poisons and Therapeutic Substances

The new (eighth) edition of the *Poisons and T.S.A. Guide* incorporates all the relevant changes that have come into effect since the publication of the previous edition in August 1964 (*Poisons and T.S.A. Guide for Pharmacists in Retail and Hospital Practice*. Pp. 234. London: The Pharmaceutical Press, 1965. 10*s*.). The new requirements of the Dangerous Drugs Act, 1965, and the Dangerous Drugs (No. 2) Regulations, 1964, so far as they affect retail and hospital pharmacists, are explained, and the three separate classes of dangerous drugs are now clearly indicated in the Extended Poisons List. The *Guide* also includes the many changes in the classification of poisons brought about by the Poisons (No. 2) Rules, 1964, and the Poisons List Order, 1965, and Poisons Rules, 1965. Included for the first time is a short summary of the Drugs (Prevention of Misuse) Act, 1964, which makes unauthorized possession of certain substances, other than dangerous drugs, an offence. Such substances are now specially marked in the Extended Poisons List. Also new is the information on the supply of animal medicines to farmers, the information on animal feeding-stuffs containing poisons and therapeutic substances, and on antibiotics for horticultural purposes and for preserving raw fish. The explanatory text of the *Guide* has been completely rearranged, and the conditions for supply of drugs over the counter and on prescription are now clearly described in the same section for each of the following: Part I and Part II Poisons; First Schedule Poisons; Dangerous Drugs; and 'Therapeutic Substances'. The *Guide* includes, for reference, the full texts of the schedules to the Poisons Rules, and the schedule to the Dangerous Drugs Act. The "Extended Poisons and T.S.A. List", thoroughly revised and brought up to date, now includes nearly 5,000 entries, with a clear indication of the particular restrictions affecting each item. The list includes, so far as possible, all affected substances, proprietary and non-proprietary, which are likely to be called for in the ordinary course of retail and hospital practice.

Spices

The aromatic, often pungent, vegetable substances used to flavour food, grouped under the name 'spices', have, by one label or another, been household words for centuries, but few people are probably aware of what a wide range of products is involved or know much about their history. Certainly, most know little of the crude methods used by natives, for example, in rural Borneo, to produce them. A forthright article by Peter Humber entitled "The Biggest Thing in Spices since Vasco Da Gama" (*Albright Magazine*, 12; December 1965. 1 Knightsbridge Green, London, S.W.1) lifts the veil from some truly amazing circumstances in which some spices are prepared and brought to market in the Far East, from first-hand information gained during a recent visit to the spice division of the firm, Stafford Allen, a member company of the Albright and Wilson Group, who have been trading in spices for 132 years. He says: "In days gone by spices were as highly prized as precious stones. Men died violently or made their fortunes in their quest for exotic seasonings. Even now spices are used as currency in primitive parts of the world and the spice business is as exciting as it ever was".

This leads to a discussion of a product known as 'Saromex', originated and marketed by Stafford Allen 10 years ago, which has already revolutionized the world's spice industry. Mr. Humber regards the production of 'Saromex' as ". . . the biggest thing that's happened to spice since Vasco da Gama rounded Cape Horn and anchored off the coast of Calicut". 'Saromex' is a natural spice extract; it contains the whole of the available aromatic ingredients, incorporated on to a clean 'spreader base' such as salt, dextrose or flour; it contains all that is desirable in a particular spice without any of the drawbacks, some of which are mentioned in no uncertain terms in his article. It is pointed out that 'Saromex' is not sold direct to the consumer but is sold and used only in large-scale food production. Of 'Saromex' spices, he says: ". . . by virtue of their standardized flavour strength and quality, manufacturers can be sure that every batch of their product will taste exactly the same, whereas with natural spices the flavour can vary enormously depending on the conditions in which the spices were grown". Despite some rather terrifying remarks concerning 'infestation' of natural spices, the point is emphasized here that normal ground or whole spices (as supplied to-day) are perfectly safe for domestic usage. This is a very interesting and, in some ways, provocative article which, however, still leaves some questions regarding natural spices unanswered. It is followed by another entitled "Experiments with Spice", in which what are called 'spice-conscious' recipes are detailed. As a practical gesture, certainly an innovation in an industrial house-journal, there is included a generous sample of 'Saromex', so that the experiments may be carried out successfully.

Geological Society of London : Awards

The Council of the Geological Society of London has made the following awards for 1966: *Wollaston Medal*, to Prof. F. R. Shepard, formerly professor of submarine geology, Scripps Institute of Oceanography, University of California, for his researches in sedimentology and submarine geomorphology, and the light they throw on

the problems of ancient rocks; *Murchison Medal*, to Prof. K. C. Dunham, professor of geology, University of Durham, in recognition of his contributions to geology and especially the study of ore deposits and their genesis; *Lyell Medal*, to Prof. S. I. Tomkeieff, professor emeritus, University of Newcastle upon Tyne, for his contributions to mineralogy and petrology and his exposition of the works of Russian geologists; *Prestwich Medal*, to Mr. D. Curry, managing director (joint), Currys, Ltd., for his work on the English Lower Tertiary rocks and his contributions to the geology of the English Channel and Western Approaches; *Wollaston Fund*, to Miss E. M. Guppy, senior experimental officer, Geological Survey and Museum, for contributions to the work of the Geological Survey, especially in petrology; *Murchison Fund*, to Prof. J. G. Ramsay, Department of Geology, Imperial College of Science and Technology, for his contributions to structural geology, particularly in the Scottish Highlands, Transvaal and the Alps; *a moiety of the Lyell Fund*, to Dr. M. J. S. Rudwick, lecturer in geology, University of Cambridge, for his substantial work in developing the field of functional morphology in palaeontology and for his contributions on the history of geology; and to Mr. J. R. L. Allen, lecturer in geology, University of Reading, for his work in sedimentology.

Philosophical Society of Washington

Dr. M. M. Shapiro, head of the laboratory for cosmic-ray physics at the U.S. Naval Research Laboratory, has been elected president of the Philosophical Society of Washington. Dr. W. J. Youden, of the George Washington University, and Dr. E. Montroll, vice-president for research at the Institute for Defense Analyses, have been elected vice-presidents of the Society.

Technion Achievement Award

The Chicago Chapter of the American Society for Technion, Israel Institute of Technology, Inc., has announced the establishment of a Technion Achievement Award. The award, including an honorarium of 1,000 dollars, will be given for some successful application of technology to an important social problem. Nominations for the Award, which will be given this year for an achievement noted in 1965, should reach Dr. Herbert H. Hyman, secretary, Technion Achievement Award Committee, 59 E. Van Buren Street, Chicago, not later than July 1, 1966.

Annual Prize for Women Undergraduates

A prize of £15 is offered by the British Federation of University Women, Ltd., for an essay on one of the following subjects: (*a*) expectation and reality on entering a University; (*b*) the responsibilities of teachers and students. Competitors should be women students reading for a first degree or diploma at any University or College of Advanced Technology in England, Scotland or Wales. Further information can be obtained from the Secretary, British Federation of University Women, Crosby Hall, Cheyne Walk, London, S.W.3, to whom entries should also be sent. The closing date for the competition is May 1.

Esso Chemical Limited

Esso Petroleum Company, Ltd., has announced that the management and operation of its present chemical business will shortly be transferred to a new company, Esso Chemical, Ltd., which will also be responsible for the future development of the chemical business of Esso in the United Kingdom. The new company will be wholly owned by Esso Chemical Company, Inc., of New York, which is in turn a wholly owned subsidiary of Standard Oil Company (New Jersey).

"A Wave Mechanical Approach to the Plasma Interaction Problems"

Prof. V. C. Liu (Department of Aerospace Engineering, College of Engineering, University of Michigan, Ann Arbor) has notified the Editor of the following corrections to "A Wave Mechanical Approach to the Plasma Interaction Problems", which appeared on p. 883 of the November 27, 1965, issue of *Nature*: "Equations (7*a*), (7*b*), (8) and (9) should read:

$$\frac{d^2\psi_1}{dx^2} + \frac{8\pi^2 m}{h^2}[Ee - \varphi(x)]\psi_1 = C_1^2\psi_1 \qquad (7a)$$

$$\frac{d^2\psi_2}{dy^2} = -C_1^2\psi_2 \qquad (7b)$$

$$|\psi|^2 = (1 - e\varphi/E\cos^2\theta)^{-\frac{1}{2}} \qquad (8)$$

and

$$x - x_0 = \int_{\varphi_0}^{\varphi} (8\pi n_0)^{-\frac{1}{2}}[2E\cos^2\theta(\sqrt{1 - e\varphi/E\cos^2\theta} - 1) - \varkappa T_e(1 - e^{e\varphi/\varkappa T_e})]^{-\frac{1}{2}}\, d\varphi \qquad (9)$$

respectively".

University News: Edinburgh

The following lecturers have been appointed: Dr. A. J. Crosbie (geography): Dr. J. S. Kelly (pharmacology). The status of reader has been conferred on the following: Dr. J. H. Bowie (bacteriology); Dr. R. M. Gaze (physiology); Dr. F. L. Mitchell (clinical chemistry); Dr. P. H. Davis (botany); Dr. J. H. Knox (physical chemistry); Dr. J. B. Sissons (geography).

London

Prof. K. G. Denbigh, at present Courtaulds professor of chemical engineering at the Imperial College of Science and Technology, has accepted the office of principal of Queen Elizabeth College in succession to Miss M. J. Sargeaunt, who will be retiring on September 30.

Newcastle upon Tyne

The following lecturers have been appointed: Dr. D. F. Roberts (human genetics); Dr. H. C. Noltimier (geophysics); Mr. P. Baldwin and Dr. J. P. Baty (engineering mathematics); Mr. A. I. B. Moffat (civil engineering materials).

Announcements

Prof. A. R. J. P. Ubbelohde has been appointed to fill a vacancy in the membership of the Agricultural Research Council, which has arisen on the resignation of Prof. W. T. Williams.

Mr. A S. Foot, head of the Department of Dairy Husbandry of the National Institute for Research in Dairying, has been appointed deputy director of the Institute.

A three-day course on "Temperature Measurement" will be held at the Woolwich Polytechnic during March 16–18. Further information can be obtained from P. R. Pallister, the Woolwich Polytechnic, Wellington Street, London, S.E.18.

A symposium on "Early Crop Production in the British Isles" will be held in the University College of Wales, Aberystwyth, on March 9. Further information can be obtained from J. A. Taylor, Department of Geography, Llandinam Building, Penglais, Aberystwyth.

A meeting of the Welsh Soils Discussion Group on "Soil as a Biological Environment" will be held at the Welsh Plant Breeding Station, Gogerddan, on February 16. Further information can be obtained from C. Rudeforth, Soil Survey, National Agricultural Advisory Service, Trawscoed, Aberystwyth.

MONOLAYERS AT LIQUID INTERFACES

AN informal discussion of the Faraday Society on monolayers at liquid interfaces was held at Loughborough College of Technology during September 9–10, 1965. The meeting was attended by 68 people, among whom there was strong representation from European research laboratories. There were 27 from industrial organizations.

The chair for the session on September 9 was taken by Dr. J. L. Moilliet (Imperial Chemical Industries, Dyestuff Division). After a brief welcome from Prof. R. F. Phillips (Loughborough College of Technology) the opening paper was given by Prof. G. M. Bell (Chelsea College of Science and Technology) and Dr. S. Levine (University of Manchester). This was concerned with the surface-free energy and the surface pressure of monolayers. The relation between the part of the surface Helmholtz-free energy, F, due to dissolved components and surface-active species, and the corresponding part of the surface pressure, Π, was discussed. When all surface-active substances are soluble in the substrate, and F is defined as the change in surface-free energy density during a process in which they are brought into the surface region from the bulk of the substrate, then it was shown that $\Pi = -F$. This is not true if any of the surface-active substances are insoluble and an expression for $\Pi + F$ was obtained in this case. The form of Π obtained in this way was shown to be identical with that derived by integration of the Gibbs adsorption isotherm (as used by Onsager and Samaras and others for air-electrolyte interfaces). The authors concluded with a brief mention of the various contributions to the spreading pressure of an insoluble partially ionized monolayer on an aqueous electrolyte substrate.

The second paper was given by Drs. J. Mingins, J. W. Brooks and B. A. Pethica (Unilever Research Laboratory, Port Sunlight) and described investigations of ionized monolayers. Previous data on the surface pressures of insoluble and soluble ionized monolayers at both non-polar oil–water and air–water interfaces were critically reviewed and compared with recent data obtained at Port Sunlight. Discrepancies among the data were discussed in terms of solution of the monolayer, poor spreading, and impurities in the surface-active agents, electrolytes and water. Results on films spread from crystals indicated that solvent retention had occurred in some of the earlier published work on gaseous monolayers spread at the air–water interface. The cohesive pressure due to hydrocarbon chain interaction was shown to be negligibly small at non-polar oil–water interfaces over the range of areas per molecule studied (50 Å^2). However, at air–water interfaces the cohesive pressure was a complex function of chain-length, area per molecule and head group. The validity of previous empirical equations describing this term was questioned.

Dr. E. H. Lucassen-Reynders (Unilever, Vlaardingen) presented a thermodynamic approach to the surface equation of state. This included consideration of ionizing surfactants and non-surface active electrolytes. The resulting equations are similar to those for non-ionizing surfactants, except that the molar concentration in the solution is replaced by the geometric mean of the product of the concentrations of the long-chain ions and counter-ions. The general equations give the surface tension as a function of the mean ionic product in terms of three types of parameters. These are, first, the interfacial activity coefficients, γ_i^s, of the surface mixture of surfactant and water; secondly, the saturation adsorption, Γ^∞ (the total values for long-chain ions and counter-ions); and thirdly, a parameter, a, measuring the free adsorption enthalpy at infinite dilution. The equations were applied to published surface and interfacial tension measurements on adsorbed and spread monolayers of long-chain alkylsulphates, trimethyl ammonium bromides and carboxylates, in the presence of various amounts of non-surface-active electrolytes. At oil–water interfaces, the ionized surfactants were shown to form ideal surfaces ($\gamma_i^s = 1$), irrespective of the presence of inorganic electrolyte with a common ion. At the air–water interfaces especially the longer-chain surfactants were shown not to form ideal surfaces. In particular, carboxylate soap solutions show regular surface behaviour. The γ_i^s values obtained from the experimental data suggested that the main factor responsible for the non-ideality of a surface was the interaction between the hydrophobic chains of the surfactant.

A further paper on the thermodynamics of interfaces was presented by Dr. A. J. Spaull (Brunel College). Methods for obtaining thermodynamic parameters for adsorption at the air–water interface were considered. It was maintained that the initial linear region of the adsorption isotherm is important, but it was suggested that use of the slope, α, of the plot of surface pressure as a function of concentration, can lead to incorrect values of the thermodynamic parameters. Analysis has shown that, to first order, the plot of the ratio of surface pressure to concentration as a function of surface pressure can be represented by the equation:

$$\Pi/c_x = (\Pi/c_x)_0(1 - a/RT)$$

where a is a two-dimensional second virial coefficient, and $(\Pi/c_x)_0$ is the extrapolated value of the ratio of surface pressure to concentration at zero surface pressure. To calculate correct thermodynamic parameters it is $(\Pi/c_x)_1$ rather than α that is required, except when a is zero. Experimental methods for testing this argument were indicated. Certain thermodynamic parameters obtained for the adsorption of 1-butanol and 1-hexanol were used to test a recent theory of Aranow and Witten, who claim that adsorption of long-chain hydrocarbons is essentially an entropic process arising from restricted rotation about carbon bonds in aqueous solution. Some difficulties of the theory in explaining the evidence of the nuclear magnetic resonance spectra of alcohol solutions and the solvation of rare gases were discussed.

Dr. J. B. Matthews (Loughborough College of Technology) proposed a new approach to the dynamics of adsorption from solution. The kinetics of adsorption from solution is still a controversial subject, owing to the uncertainties associated with the experimental data and the model for the adsorption process. A number of theories for the kinetics of adsorption have culminated in the Ward–Tordai theory, which now receives general acceptance, either in its original form or as modified by others. The model proposed by Ward and Tordai assumes the existence of a sub-surface from which solute molecules are adsorbed instantaneously and irreversibly to the surface, if there are available sites for them. The kinetics of adsorption are assumed to be controlled by the diffusion of solute molecules to the sub-surface from the bulk of the solution. Dr. Matthews stated that this model ignores the dynamic character of adsorption and transitions between the possible states of adsorbed molecules. The mathematical treatment of this model leads to kinetic results which are more consistent with experimental data than the Ward and Tordai theory.

The chairman for the second day was Prof. D. D. Eley (University of Nottingham). In opening the session Prof. Eley paid tribute to Dr. J. J. Kipling, who was a member of the organizing committee of the discussion and whose untimely death occurred at a conference in Moscow earlier in the year.

The first paper was given by Prof. A. Scheludko (Institute of Physical Chemistry, Sofia, Bulgaria), who reported work carried out with Dr. D. Tissen on the damping of ripples on water by soluble surfactants and insoluble monolayers. A novel apparatus has been developed for this problem, consisting of a cylindrical vessel in which standing waves are generated by a vertical sinusoidal vibration. The amplitude of ripples smaller than 30μ could be determined optically with an accuracy of 1 per cent and the damping measured by changing the energy supplied to the vessel. Results were presented for the damping coefficient as a function of concentration (or area) for caproic, capric, myristic, palmitic and propyldodecyl acetic acids and for cetyl alcohol on water. With all except the first, a sharp maximum was found at intermediate surface densities and damping coefficients at the maximum exceeded (for a factor of 2–3) the value predicted by the hydrodynamic theory of Levich for damping by a condensed monolayer.

The next paper, by Drs. J. M. Corkill, J. F. Goodman, S. P. Harrold and J. R. Tate (Procter and Gamble, Newcastle upon Tyne), was concerned with mixed monolayers of both soluble and insoluble salts of the type alkyltrimethylammonium-alkyl-sulphate at the air-solution interface. Insoluble monolayers were examined using a Langmuir trough. It was demonstrated that although second-order effects are present due to the substrate or the particular molecular species involved, maximum interaction invariably occurs at a 1 : 1 ratio of long-chain cation to anion. The composition of the surface layers of the soluble members was measured by radio-tracer techniques. When the long-chain cation and anion had the same chain-length an equimolar surface composition was obtained. However, if the ions had different chain-lengths, the longer chain ion was preferentially adsorbed giving an asymmetric surface layer, the asymmetry being enhanced by the addition of inorganic electrolytes. It was concluded that adsorption is promoted principally by the elimination of alkyl chain–water interface, but this is modified by the electrical interaction between the positive and negative head groups, which is a maximum when the surface composition is equimolar.

A paper by Dr. J. J. Kipling and Dr. C. A. J. Langman (University of Hull) dealt with the surface tension of two component liquid mixtures and the adsorption from these mixtures at the liquid–vapour and liquid–solid interfaces. The surface tensions of a number of binary liquid mixtures of molecules of similar sizes were measured and the results were shown to fit quite well an equation based on a regular solution model, relating surface tension to composition. The adsorption from the mixtures at low-energy solid surfaces was studied and the surface excess of the more strongly adsorbed molecule compared with the corresponding surface excess at the liquid–vapour interface. In all cases presented, these two excesses were similar in magnitude.

Another paper on the surface tensions of binary liquid mixtures, by Dr. R. Aveyard (University of Cambridge), concluded the conference. The surface tensions of a range of two-component mixtures of *n*-alkanes have been measured. The applicability of various equations to the experimental data was tested and it was found that a theory, devised by Prigogine and Maréchal for athermal polymer solutions, was the most satisfactory of those considered. Using this theory, the surface tensions of all the mixtures investigated could be predicted to within 1·0 per cent with the use of physically realistic and self-consistent parameters. Further, the applicability of this theory to the surface tensions of methanol–*n*-decanol and methanol–glycerol mixtures was tested. The agreement between experiment and theory was poor for the former system, but reasonable for the latter. A possible explanation for these differences, and its bearing on the agreement obtained for the *n*-alkane systems, was discussed.

PHYSICS IN MEDICINE

TECHNOLOGY, rather than science, was the main theme of the first International Conference on Medical Physics, held at Harrogate during September 8–10, but several topics of a more fundamental kind were also illuminated in a programme of more than 100 papers. A majority of the contributions dealt with the clinical and biological applications of ionizing radiations, reflecting a continuing preoccupation with the problems which brought physicists into the hospital service in significant numbers some 30 years ago.

Though the radiotherapist's armamentarium has not changed substantially in recent years, two areas of research at present give promise of greater accuracy in the measurement and control of radiation dosage for clinical purposes. The first problem here is to find a device of small size (preferably in the millimetre range) with a sensitive response independent of radiation energy. Lithium fluoride dosemeters, based on the thermoluminescent effect, satisfy these requirements reasonably well. Large-scale practical applications are, however, restrained by inadequate understanding of the basic processes involved. The preparation of lithium fluoride powder and its treatment before and after irradiation are still largely determined by empirical knowledge, which necessitates caution in the interpretation of experimental findings.

Thermoluminescent dosemeters have been used for the estimation of surface dosage in radiotherapy, but not so far for internal measurements. F. W. Spiers (General Infirmary, Leeds) described methods for the study of radiation dose in specimens of dry bone, using fine-grain lithium fluoride powder which is introduced into the narrow cavities of trabecular bone and removed for assay after irradiation. Work of this kind is useful in assessing clinical, occupational and environmental hazards from radioactive materials. B. E. Bjarngard (Controls for Radiation, Inc., Cambridge, Massachusetts) reported that some of the difficulties associated with the preparation and handling of thermoluminescent powders may be avoided by incorporating the lithium fluoride phosphor in polytetrafluorethylene, which can then be fashioned into rods, disks or foils for various applications. The combination has an effective atomic number close to that of tissue, and its response is independent of radiation energy over a fairly wide range.

Interesting applications are now being found for solid state devices as radiation detectors. P. R. Parker (Institute of Cancer Research, Sutton, Surrey) suggested that many of the desirable properties of the gas-filled ionization chamber may be reproduced, with the advantage of very small bulk, by *p–n* surface barrier detectors. Used as pulse counters, these devices will measure dose-rates of about 10 μrad/h, approximately equal to the natural background radiation in Britain. The radiation-induced potential across the *p–n* junction is found to be a logarithmic function of dose-rate and the short-circuit current is approximately a linear function of dose-rate. Silicon

surface barrier detectors offer high sensitivity in small size and may be useful in estimating radiation dosage (from internally administered isotopes) inside the body. The field effect transistor, having high input impedance and high transconductance, may replace an electrometer valve in the input stage of a current amplifier used, for example, in association with an ionization chamber. J. Keller (Central Laboratory for Radiological Protection, Warsaw) described an amplifier, using a single transistor, with a gain of 5×10^5 and excellent temperature stability.

A second problem of immediate interest in radiotherapy concerns the use of electronic computers to tackle the tedious calculations involved in treatment planning and dosage control. The great output delivered by machines such as the linear accelerator makes rapid arithmetic essential, and the complexities of radium dosage are not always adequately recognized in the rules or methods based on manual calculation. Papers presented at the Harrogate Conference showed a relatively unsophisticated approach to these problems and left the impression that a much larger effort is needed (from mathematicians as well as from physicists) if the computer is to make a realistic contribution to the technique of radiotherapy.

Diagnostic and physiological investigations using radioactive tracers are now commonplace, though still capable of extension in a number of clinical specialities. Interesting technical problems are met with in the design and operation of whole-body monitors. In measuring the natural radioactive content of the body (for example, potassium-40 as an index of lean body mass) elaborate electronic equipment and a well-shielded room will be necessary, at a cost which may approach £30,000. When it is desired to investigate, over a period of months, the retention of a particular isotope in the body, a simpler installation can be built for £2,000–£5,000.

Though knowledge of the whole-body content of an isotopic tracer is important, a detailed picture of the distribution in a particular organ or region may be significant (for example, in thyroid disease or in the localization of a tumour). The scintillation scanner and the scintillation camera (which uses the principle of the pinhole camera) are well known in this connexion. Another basically simple device, likely to have useful applications in clinical science, is the spark chamber. The design described by B. R. Pullan (St. George's Hospital, London) has two parallel plates, one of lead and one of aluminium mesh, in an enclosure filled with argon and alcohol vapour. When an appropriate potential difference is maintained between the plates, a spark will occur wherever ions are produced in the gas. A chamber of this kind (used in conjunction with a suitable collimator) should be useful in thyroid studies with radioactive iodine as a tracer.

Among the other topics discussed were (*a*) the use of analogue computers and mathematical models in the study of renal function, urinary excretion and control of ventilation, (*b*) objective measurement of X-ray image quality, (*c*) electron spin resonance in living tissue. A series of eight survey papers, illuminating areas of common interest among physicists, biologists and clinicians, included an interesting account by S. Rowlands (St. Mary's Hospital Medical School, London) of basic studies on blood flow. The apparent viscosity of blood depends on its composition and on the shear rate applied in the experimental equipment. These properties are shared by other biological materials and non-Newtonian fluids. Blood has a unique property, discovered by measurement of flow rates through tubes of less than 0·5 mm diameter. Here it is found that the narrower the tube the smaller the apparent viscosity. It seems likely that hydrodynamic forces drive the red cells from regions near the wall (where the shear rate is high) into the central stream, where the shear rate is lower. In very narrow tubes, of diameter comparable with the diameter of a red cell, further complications occur and the deformability of the cell has an important influence on flow phenomena.

In the realm of medicine there is abundant opportunity for work of social and economic value, amply testing the physicist's experimental skill and mathematical insight. In several countries (including Britain) this opportunity is not being sufficiently exploited at the present time. Many hospital physicists are dispersed in small departments, mainly occupied with work related to the practice of radiotherapy, and not adequately equipped (with staff, material resources and scientific contacts) for work of more basic importance.

During the next decade, it seems likely that the large and well-justified expenditure from public funds in support of scientific research in universities and government laboratories will come under closer scrutiny and its continued growth may even be restrained. If, in these circumstances, some of the less costly fields of endeavour receive increased attention, the collaboration of physics and medicine might be cultivated with advantage to the world of science and to the whole community.

J. M. A. Lenihan

ENERGY SPECTRUM OF PRIMARY COSMIC-RAYS

By P. K. MALHOTRA*, P. G. SHUKLA, S. A. STEPHENS and B. VIJAYALAKSHMI
Tata Institute of Fundamental Research, Bombay
AND
M. G. BOWLER, Dr. P. H. FOWLER, F.R.S., H. L. HACKFORTH, J. KEEREETAVEEP, V. M. MAYES and S. N. TOVEY
H. H. Wills Physics Laboratory, University of Bristol, England

During the past decade or so, several measurements have been made of the flux of the cosmic-ray particles in the wide range of energy from 10^9 to 10^{20} eV. These were based at the lower energy end on the flux of nuclei observed at different geomagnetic latitudes and at energies greater than 10^{15} eV on the results of extensive air shower experiments. The data in the intermediate energy range were not so reliable. The pioneer experiments of Lal[1] and Kaplon and Ritson[2], which have played a useful part in giving an estimate of the primary flux in the energy region 10^{12}–10^{13} eV, made use of detectors of alternate sheets of 3 mm brass and 100 μm *G*5 emulsions mounted on 1·3 mm glass. In such a detector the distinction between electromagnetic cascades initiated by electrons or γ-rays entering from outside and those resulting from interactions of nuclear active particles in the detector itself could be quite ambiguous. Further, energy estimates were rather unreliable and the results were based on a small number of events. Values of the flux, at 4×10^{13} and 2×10^{15} eV, due to Barrett *et al.*[3], were obtained from underground measurements on μ-mesons, and therefore depend on the assumed model of high-energy interactions. This article presents our results on the primary flux, both

* Now at Northwestern University, Evanston, Illinois, U.S.A.

of protons and heavier nuclei, in the energy range $2{\cdot}6 \times 10^{12}$–$2{\cdot}6 \times 10^{14}$ eV, and makes a comparison with other results over the entire range 10^9 and 10^{20} eV. At the lowest energies, the charge composition of the primaries is well known[4] and in our work some direct evidence on heavy nuclei also may be obtained. Extensive air shower experiments measure the flux of all nuclei above a given total energy and there is no direct evidence that the charge composition of the primaries is the same as at 10^{10} eV. We have, therefore, chosen to present a spectrum of all nuclei above a given total kinetic energy as distinct from kinetic energy per nucleon. The difference between the kinetic energy, E, and the total energy, T, is insignificant except at the very lowest energies considered where the former is a more informative quantity.

In our experiment, we used a tungsten-emulsion assembly of area $0{\cdot}7$ m^2, eight radiation lengths thick. This was flown for 28 h at an effective atmospheric depth of 22 g cm^{-2} (ref. 5). The assembly provided an efficient detector of electromagnetic cascades. As already described[5], the distinction between cascades initiated by electrons or γ-rays entering from outside and those from nuclear active particles interacting in the detector was good. Further, the cascade energy could be quickly and accurately obtained from photometric measurements of the density of electron tracks near the cascade axis. A total of 527 nuclear events, satisfying certain geometrical selection criteria and having a total cascade energy ($\Sigma E\gamma$) of more than 370 GeV, were recorded. Of these, 46 events originated in emulsion and the remainder originated in the tungsten sheets.

It is necessary to estimate the charge composition of the primary particles initiating interactions in tungsten. We assume that the interaction lengths and fragmentation parameters of multiply charged nuclei are the same as at low energies[4], and that the interaction length of nucleons in graphite is 73 g cm^{-2}. We take the attenuation length of nucleons in air to be 125 g cm^{-2} and their interaction length in the detector to be the geometric value, 14·5 cm. (*Note:* The value of 14·5 cm (or 176 g cm^{-2}) for the interaction length in the detector was obtained on the assumption that the interaction cross-sections of protons with different nuclei at these energies are the same as those observed at 24–30 GeV; an $A^{2/3}$ dependence was assumed wherever extrapolation was required. This value was checked experimentally using the depth of origin of events within the detector and was found to agree within 15 per cent.) The charge composition was then estimated in two ways: (*a*) From the observed charge composition of the forty-six emulsion events (thirty-four due to protons, three due to neutral particles, presumably neutrons, six due to α-particles and three due to heavy nuclei). (*b*) By assuming that at high energies the charge composition at the top of the atmosphere is the same as at low energies.

These two estimates are in good agreement and we find that the latter method also reliably predicts the charge composition of the observed events in the ICEF Collaboration[6]. There is thus no evidence that the charge composition is different from that observed at 10^{10} eV and we assume that the relative proportions of protons, α-particles and heavier nuclei are also fairly independent of energy in the range 10^{10}–10^{14} eV. We estimate that, of the observed tungsten events, 66 per cent are due to primary protons, together with nucleons from the interactions of these protons in the atmosphere, 13 per cent are nucleons from the fragmentation of nuclei with $Z \geqslant 2$, 15 per cent are due to α-particles and 6 per cent are due to heavier nuclei.

We find that the rate of production of cascades of total energy greater than 370 GeV by protons at the top of the atmosphere is $(1{\cdot}2 \pm 0{\cdot}3) \times 10^{-8}$ per sterad sec per gram of the detector (predominantly tungsten). We cannot exclude a systematic error in the energy determination of up to 15 per cent. This leads to the 25 per cent error quoted here, compared with which the statistical error is negligible. The integral energy spectrum of nuclear cascades[5] can be represented by a power law of the form $(\Sigma E\gamma)^{-1.44 \pm 0.05}$ in the range $370 \leqslant \Sigma E\gamma < 3 \times 10^4$ GeV.

To transform the cascade energy to primary energy we assumed that $E = 7\Sigma E\gamma$; this corresponds to $K\pi = 0{\cdot}43$ and $K\gamma = K\pi/3$. Dobrotin and Slavatinsky[7], working at 300-GeV primary energy, obtained a mean inelasticity $K\pi = 0{\cdot}35 \pm 0{\cdot}05$, and the foregoing figure was derived from their result allowing for the fact that the primary spectrum is a power law and that events are detected by their cascade energy. To obtain the flux of primary protons we have multiplied the production rate by the interaction length for protons in the detector (see '*Note*' above), 176 ± 26 g cm^{-2}. We thus obtain in the range $2{\cdot}6 \times 10^{12}$ to $2{\cdot}6 \times 10^{14}$ eV the expression

$$n(>E) = (1{\cdot}6 \pm 0{\cdot}5) \times 10^{12}\, E^{-1.44}, \text{ where } E \text{ is in eV}$$

The charge composition being taken to be that observed at lower energies, the flux of all nuclei at the top of the atmosphere above the same total energy is double this flux. About half these multiply charged primaries are α-particles and half are heavier nuclei. Thus, in Figs. 1 and 2, our results for the flux of all nuclei are represented by:

$$N(>E) = (3{\cdot}2 \pm 1{\cdot}0) \times 10^{12}\, E^{-1.44}$$

Fig. 1 is the spectrum of the number, N, of all nuclei above a given kinetic energy, E, in a conventional plot. The scale is so small that it is difficult to both present errors and to read values from it. We therefore give Fig. 2 in which the same data are plotted in the form log $(NE)^2$ against log E; in Fig. 2 a horizontal line corresponds to a spectrum of negative index $\gamma = 2{\cdot}0$.

In Figs. 1 and 2, the curves marked (1) represent the results of many workers as reviewed by Waddington[4]; we assume that the charge composition of the primaries does not change in this energy region and that the spectrum of total energy between 1·3 and 100 GeV is a power law of index $\gamma = 1{\cdot}50$ with a cut off below 1·3 GeV/nucleon. Lal[1] and Kaplon and Ritson[2] measured the proton flux, and their results have been scaled by the factor of 2·0 to allow for other nuclei. Baradzei *et al.*[8] used ionization chambers and observed the energy radiated as γ-rays in the interactions of nuclear active particles with carbon

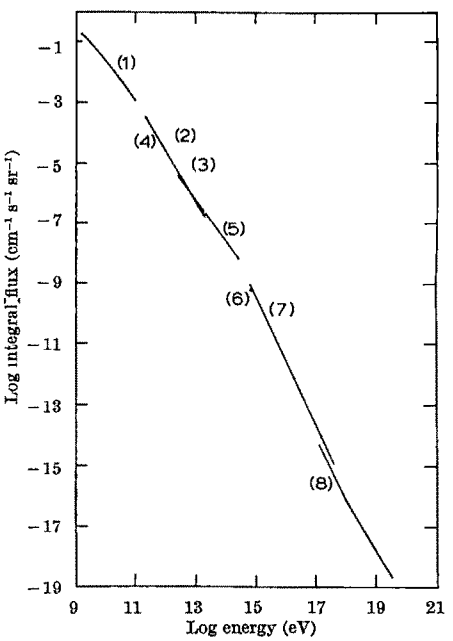

Fig. 1. Integral energy spectrum of all nuclei incident on the atmosphere. The data are collected from (1) geomagnetic measurements as reviewed by Waddington, 1960, (2) Lal, 1953, (3) Kaplon and Ritson, 1952, (4) Baradzei *et al.*, 1962, (5) present experiment, (6) Zatsepin *et al.*, 1963, (7) Clark *et al.*, 1963, (8) Linsley, 1963

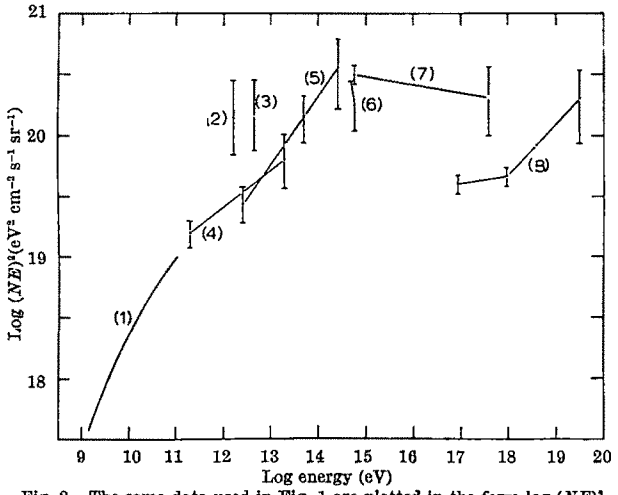

Fig 2 The same data used in Fig. 1 are plotted in the form log $(NE)^3$ against log E. A horizontal line in such a plot would correspond with a spectrum of negative index $\lambda = 2{\cdot}0$

at an atmospheric depth of 200 g cm^{-2}. The flux obtained by them refers to all nucleons; in order to obtain the flux of all nuclei we have increased it by a factor of 1·5 (this figure is the product of 0·75—ratio of protons to all nucleons—and 2·0—ratio of all nuclei to protons).

Finally, above 10^{15} eV, we give the results of Zatsepin *et al.*[9], Clark *et al.*[10] and Linsley[11]; these results are as given by their authors. The difference between the fluxes reported by Zatsepin *et al.* and Clark *et al.* at 6×10^{14} eV may be partially due to the different factors used by the two groups in converting number of particles into primary energy (1·7 and 2·0 GeV per particle respectively).

The present results, and those of Baradzei *et al.*, confirm that the flux values given by Lal and by Kaplon and Ritson are overestimates. It now seems clear that the energy spectrum cannot be represented by a single power law over the energy range 10^{10}–10^{20} eV. Between 10^{11} and 6×10^{14} eV it is consistent with a power law of negative index $\gamma = 1{\cdot}60 \pm 0{\cdot}02$ and the flux of all nuclei is:

$$N(>E) = (3{\cdot}9^{+3{\cdot}4}_{-1{\cdot}8}) \times 10^{14} \times E^{-1.60}$$

where E is in eV. (Preliminary results on the flux of all nuclei measured above the atmosphere in the satellite *Proton I* indicate a much lower flux (between 10^{10} and 10^{13} eV) than those quoted in this article. The results, communicated by Prof. Grigorov at the London Conference of the International Union of Pure and Applied Physics, September 1965, are a factor of about 7 lower than the results given here. It is as yet uncertain whether the difference arises from the observed flux or the measurement of primary energy.) Above 10^{15} eV the spectrum is significantly steeper and, at the very highest energies recorded, there is disagreement as to the absolute value of the flux.

GENESIS OF RAPAKIVI

By PETER R. DAWES

Department of Geology, University of Exeter, Devon

A REVIEW of the work on the Pre-Cambrian basement of South Greenland has recently been published[1]. Investigations in the Tasiussak area (Fig. 1), carried out under the auspices of the Greenland Geological Survey, have revealed a rapakivi granite massif displaying clear and distinctive features. Excellent exposures on the glaciated southern Greenland coast allow deductions on rapakivi genesis to be made, and these are set out below.

There is a general consensus of opinion at the present time that rapakivi granites crystallized from magma at high crustal levels[2] and it is widely accepted that one of the peculiar textural characters of rapakivis (the occurrence of big mantled felspars) is a direct result of the crystallization of magma. It is this conclusion which is challenged here. The Tasiussak massif is a rapakivi in which basic rocks were emplaced during the genesis of the granite, and it is by means of these basic rocks that two stages in rapakivi development can be demonstrated, with the typical texture a product of post-magmatic metasomatism.

Rapakivi, a term derived from the Finnish '*rapautuwakivi*' ('disintegrating rock'), was adopted by Sederholm[3] for a particular set of Pre-Cambrian granites in Finland which, while displaying their vulnerability to weathering processes, were also linked by petrological characteristics. These characteristics include post-tectonic intrusion and a porphyritic texture formed of ovoid crystals of potash felspar each mantled by a shell of oligoclase. The latter feature has become known as 'rapakivi texture'. Many rapakivi

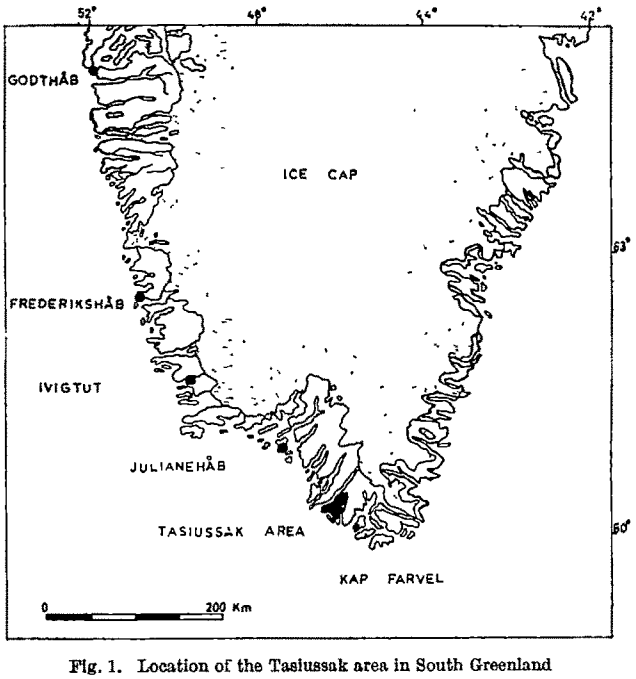

Fig. 1. Location of the Tasiussak area in South Greenland

granites, however, do not display prominent mantling of potash felspar crystals, and there is a transition from rapakivi granites in which the majority of the potash felspar megacrysts are mantled (for example, most of the Finnish rapakivis), to those in which only a few felspar individuals have an oligoclase shell (for example, the Swedish rapakivis). Terzaghi[4] restricts the use of the term rapakivi to granites characterized by mantled felspars, while von Eckermann[5] and Savolahti[6] do not regard this to be an essential feature and point to the importance of two generations of quartz, potash felspar and plagioclase.

The Tasiussak rapakivi covers an area of about 120 km. It post-dates the formation of the Ketilidian granulite facies gneiss and granites and the early Sanerutian granite with its associated aplites and pegmatites[7]. It has sharp, discordant contacts to the country rocks and is ethmolithic. The rock is a biotite–hornblende granite with felspars which vary from mesostasis size up to megacrysts 17 cm long. The megacrysts vary in shape from ovoid to euhedral, and they commonly display a mantling of oligoclase-albite. Concentric rings of oligoclase-albite are occasionally present in both ovoid and well-shaped megacrysts. In places the abundance of megacrysts is so high that the crystals have coalesced to form a continuous network with the groundmass of the granite occupying interstitial spaces. Such a fabric approaches the equilibrium texture of Voll[8]. The microcline of the megacrysts is perthitic, the string and patch perthite of Andersen[9] being the most common form. An earlier generation of potash felspar occurs in the groundmass, but this is in smaller grains and is non-perthitic. Early forming albite occurs in the groundmass and quartz forms at least two generations, first in the groundmass and later genetically connected with myrmekite in association with the microcline megacrysts.

The granite lacks an overall foliation or lineation, but it has widespread occurrences of oligomict and polymict inclusion-breccias composed of the principal rock types of the country rocks. These are quartz-felspathic gneiss, pelitic gneisses and schists, pyriclasites, pegmatites, quartzites (including psephites) and earlier granites. Local basin-shaped layering occurs. The breccias are indicative of strong movement since in the polymict types inclusions of different compositions have been aligned and drawn out. The inclusions, commonly elongated or spindle-shaped, are aligned with their long axes parallel in the form interpreted by Balk[10] as showing that they were "rotated by the magma current until they reached the position of kinematic equilibrium". Rotation of enclaves in the oligomict breccias is further indication of magmatic conditions. The local basin-shaped layering indicates settling under gravity of mafic minerals in peaceful conditions. Similar layering has been described by Harry and Emeleus[11] in other granite massifs in South Greenland.

From the structure it is concluded that the granite came into existence by an intrusion of magma into older Ketilidian gneisses and granites producing the typical sharp, discordant contacts to the country rocks. During this mobile stage the inclusion-breccias were formed when little crystallization had taken place and this was followed by quiet conditions permitting mafic layering and finally the main crystallization of the granite.

A dolerite-gabbro-norite suite of rocks was intruded as dykes and small bodies into the granite after the formation of the inclusion-breccias and the initial mobility. These were net-veined by acid material before their complete consolidation, and they also underwent later granitization. A critical fact is that these basic rocks pre-date the formation of the felspar megacrysts of the granite—a felspathization which resulted in the contacts between the basic rocks and the granite and the basic rocks and the net-veins being locally obscured. Felspar megacrysts are present in the basic rocks either singly or in clouds in a situation which excludes all possibility of magmatic formation either by direct crystallization from a magma or by diffusion of alkalis from the magma, since the crystallization of the granite was complete before the basic rocks were intruded.

'Rapakivi texture' has from the early days of granite research drawn the attention of many workers, and Sederholm[3,12], Holmquist[13], Vogt[14], Harker[15], Wahl[16], Popoff[17], Hackman[18], von Eckermann[5], Terzaghi[4], and recently Gates[19], Savolahti[3,6], Stewart[20], Tuttle and Bowen[21] and Marmo[22] have all concluded that the texture is directly bound up with the crystallization of magma. Experiments by Tuttle and Bowen[21] have confirmed the earlier work of Gates[19] on the crystallization of 'rapakivi magma', and they conclude that, since the rapakivi granites are richer in potash than the average granite, their composition lies in the alkali felspar field, and thus alkali felspar crystallizes before plagioclase. This sequence of felspar crystallization has been grasped as the significant feature in the genesis of rapakivi granites, and ideas from it have been adopted to explain the texture. Typical of these is the comment of Savolahti[6]: "As a consequence of the inverse crystallization of the rapakivi magma, the rapakivi structure and texture and the formation of the potash feldspar ovoids enveloped in a plagioclase shell are self-evident". While the possibility of mantling resulting from magmatic crystallization is not disputed, it is evident from the Tasiussak rapakivi, which is strikingly similar to the celebrated rapakivis of Fennoscandia, that this is a post-magmatic phenomenon. How do the theories of Stewart[20], Tuttle and Bowen[21], or Savolahti[6] explain the potash felspar–plagioclase relationship in a non-magmatic environment?

'Rapakivi texture' occurs in both the felspars of the granite and in the basic rocks and inclusions in the granite. In all these milieu the relationship of the potash felspar to the plagioclase is identical. The albite-oligoclase of the mantles and of the concentric rings in the megacrysts is in optical continuity with the plagioclase of the perthite, and there is evidence to indicate that the plagioclase of the mantles has locally replaced the microcline. It is considered that the formation of the plagioclase of the perthite and that of the 'rapakivi texture' has taken place by the same process; that is, exsolution during an overall post-magmatic potash metasomatism (see Eskola[23]).

It has been demonstrated by Tuttle and Bowen[21] that the alkali felspars form a complete solid solution series above 660° C and at lower temperatures homogeneous synthetic felspars unmix to give perthite. Spencer[24] has shown that up to 30 per cent of soda can be accommodated into solid solution within the potash felspar at a temperature of 700° C, and it is also known from the work of Tuttle and Bowen[21] that the unmixing and mixing of alkali felspar are readily reversible and dependent on water vapour and composition of the felspar. It is postulated that due to the fluctuating temperature in the late stages of the rapakivi genesis during potash metasomatism a number of exsolutions occurred which produced the perthite and the 'rapakivi texture'. The concentric rings of plagioclase represent retarded exsolutions, and the mantles the final exsolution to attain equilibrium.

Many theories have been advanced to account for the rounded shape of the felspar megacrysts of rapakivi, including impurity of the felspar[3], liquation[13], resorption[20], corrosion[14], and viscosity of the magma[12]. Savolahti[3] relies on four processes: slowness of diffusion, the slow and balanced crystallization, corrosion and automorphic processes. The megacrysts of the Tasiussak rapakivi have grown in the solid state, and the theories of magmatic origin are thus untenable. The observation of Sederholm[12] that only those crystals which are ovoid display 'rapakivi texture' is not universal, and in the Tasiussak rapakivi mantling occurs in both euhedral and non-euhedral megacrysts. The relationship between mantling and shape is thus not genetic. The presence of concentric rings of plagioclase in some megacrysts indicates that the two extremes of crystal shape persisted throughout growth.

It seems that the shape of the megacrysts was controlled by the immediate environment, and in places there has been coalescence to form a network. Buerger[25] discusses the problem of crystal form, and draws inferences from the crystallization of metals, suggesting that crystals without faces are quite normal under certain conditions. The presence of crystal faces in effect depends on the surface energy of the growing crystal and that of the milieu, and if a crystal develops in a medium the surface tension of which is equal to its own it is impossible for crystal faces to develop. Similar explanations have been used by Harker and Parker[26] for the polygonal shape of crystals. In the Tasiussak rapakivi, there is a range in megacryst shape from rounded to polygonal and euhedral, and it is suggested that conditions of equal surface tension between the environment and the growing crystal enable ovoidal crystals to form. This condition is realized in cases where felspar growth has been profuse and the fabric approaches the equilibrium texture of Voll[8].

The development of the Tasiussak granite can thus be divided into two stages: the magmatic stage giving rise to its form with discordant and sharp contacts, inclusion-breccias and mafic layering; and the non-magmatic stage producing the observed granite texture. The distinction between the magmatic and non-magmatic effects is clear and recognizable. The striking similarities between the Tasiussak rapakivi and the other rapakivis of the world, in particular the celebrated Fennoscandian and North American examples, suggest that this mode of origin operated generally but the stages have not been recognized because of the absence of comparable basic rocks. Basic rocks occur in association with other rapakivis of the world, but their relation to the granite is not the same as in the Tasiussak area. Sederholm[27] recognized basic intrusions both before the youngest and after the oldest rapakivi granite in some of the Finnish massifs, and Savolahti[6] has demonstrated from the Ahvenisto massif that a suite of olivine diabases was emplaced after the formation of the biotite rapakivi but before the intrusion of the hornblende rapakivi; but the formation of the first was complete before the basic rock intrusion. In contrast, the basic rocks of the Tasiussak granite were emplaced during rapakivi genesis.

The final comment might be reserved for Spencer[28], who states: "The occurrence of potash–soda porphyroblasts in xenoliths and similar metamorphosed rocks, under conditions which preclude an origin by direct crystallization from a magma, raises the question as to how far it is justifiable to regard holocrystalline rocks, even of typical granitic appearance, as products of direct magmatic crystallization". The Tasiussak rapakivi with the occurrence of basic rocks enables the magmatic effects to be distinguished from the later non-magmatic. The Fennoscandian and North American rapakivis without similar basic rocks, but with felspar megacrysts in xenoliths and the country rocks, have hitherto been regarded as products of direct crystallization from a magma.

Thanks are due to K. Ellitsgaard-Rasmussen, director of the Greenland Geological Survey, for permission to publish this work, and to Dr. K. Coe, University of Exeter, for advice.

ODOUR AND MOLECULAR VIBRATION

By R. H. WRIGHT
British Columbia Research Council, Vancouver

A MOLECULE is an assembly of mass points and elastic forces, and when energy is put into it, it vibrates in various more or less complicated ways. The complex oscillations can, however, be analysed into a finite number of vibratory motions which are mutually independent (in the absence of substantial anharmonicities) and which constitute the 'normal modes' of the molecule. Each has a specific period and frequency which can be deduced from its spectra—at least in simple cases.

Until now, all attempts to show that vibrations are osmically specific have used either the observed spectroscopic frequencies or the more refined normal modes deduced from them, and these attempts have been quite unsuccessful. Table 1, for example, shows the normal

Table 1. NORMAL MODES
100–500 cm^{-1}

C_6H_5-CN	C_6H_5-NO_2	C_6H_5-CHO
462	420	450
401	397	437
381	255	402
172		237
162	176	226
	139	130

modes for three substances with nearly the same almond-like odour, and quite evidently there is no substantial correlation.

This may be because the vibrational hypothesis of odour causation is wrong, or it may be because something important has been overlooked. That something appears to be the possibility that two normal modes can be excited in the same molecule at the same time. Thus, if a molecule has, for example, normal modes at 150, 200 and 400 cm^{-1}, each of these modes can be activated by collision at room temperature. Each of the modes can be populated. But—and this is the factor that has been overlooked until now—more molecules will be populated simultaneously in the 150 and 200 cm^{-1} modes than in the 400 cm^{-1} mode. Furthermore, when two normal modes are excited in the same molecule, the result must be a new frequency which is the difference between the frequencies of the two normal modes.

In terms of osmics, what is concerned here is the frequency of the vibrations that are actually occurring, that is, the populated energy-levels, and so the difference frequencies as well as the normal mode frequencies must

be taken into account—the basic requirement being that they must be populated at ordinary temperatures.

Benzonitrile is a substance with bond-defined molecules and known normal-mode frequencies—and it has a distinctive bitter-almond smell. Its possible 'populated frequencies' between 100 and 500 cm^{-1} are shown in Table 2. If the vibrational hypothesis is correct, some, but not necessarily all, of these numbers must hold the key. To identify the osmically active frequencies, we collate them with similar values for nitrobenzene and benzaldehyde, which have rather similar odours.

The frequencies that are common to all three fall near 175, 225 and 400 cm^{-1} and the agreement is within about 1 per cent, which is quite close. There are, however, many additional frequencies which conform to no pattern. Let us call them 'osmically inactive'. The first thing to note is that in benzonitrile, for example, if the 462 cm^{-1} frequency is called osmically inactive, all the difference terms that depend on it can be eliminated without destroying the pattern; and the same is true for the other 'inactive' modes.

Table 2. Normal Modes and Populated Combinations 100–500 cm^{-1}

C_6H_5-CN	C_6H_5-NO_2	C_6H_5-CHO

C_6H_5-CHO		
450	Ring deformation, out-of-plane	Inactive ?
437	,, ,, in-plane	Inactive
402	,, ,, out-of-plane	Active
237	,, ,, in-plane	Inactive
226	,, ,, out-of-plane	Active
130	Side-chain, torsion	Inactive

Table 3 shows the assignments that various authorities have made to the 'active' and 'inactive' normal modes, and an interesting regularity is immediately apparent. All the osmically active frequencies are out-of-plane deformations of the benzene ring which is the main part of the molecule. Almost all the inactive modes are either in-plane ring deformations or localized oscillations of the side-chain. This does not apply to the 450 cm^{-1} mode of benzaldehyde, and it is not quite clear how far it is true for the 420 cm^{-1} mode of nitrobenzene, so that their inactivity is open to some question. This does not destroy the basic pattern and, in fact, the odours of nitrobenzene and of benzaldehyde are not exactly identical.

There is nothing intrinsically improbable in this apparent association of osmic activity with out-of-plane oscillations of these molecules. Benzene rings with these side-chains might be expected to lie flat when adsorbed on the receptor surface, and from this it is, perhaps, possible to deduce three criteria of osmically active vibrations: (1) they must have low frequency; (2) they must involve all or most of the molecule; (3) they must have substantial components perpendicular to the receptor surface.

Information theory suggests that the whole gamut of smells is derived from about twenty-five primary odours. If the almond odour is due basically to these three frequencies it is a three-primary odour. We can tentatively estimate the band-widths by dividing the 100–500 cm^{-1} region logarithmically into this number of non-overlapping intervals, in which case the frequency-specification of the almond odour is the simultaneous presence of osmically active vibrations falling roughly in the ranges 170–182, 218–232 and 380–405 cm^{-1}. Other odours would presumably correlate with other combinations of frequencies, but this is still to be demonstrated.

The odours of acetophenone and of phenyl isothiocyanate include an almond 'note', together with other 'notes' sufficient to modify, but not wholly disguise, the almond character. Table 4 shows their populated vibrational levels in the 100–500 cm^{-1} range. When the in-plane and the localized oscillations are taken out, using vibrational assignments from the literature, Table 5 shows the result.

Table 4. Normal Modes and Populated Combinations 100–500 cm^{-1}

C_6H_5-NCS	C_6H_5-$COCH_3$
491	464
437	406
396	366
355	301 (464–163)
257 (437–180)	243 (406–163)
245	225
216 (396–180)	203 (366–163)
180	181 (406–225)
175 (355–180)	163
151 (396–245)	141 (366–225)
110 (355–245)	

Table 5. Out-of-Plane Frequencies

C_6H_5-NCS	C_6H_5-$COCH_3$	
	LeBas[1]	Delorme[2]
491	464	464
437	406	406
396	301 (464–163)	366
311 (491–180)	243 (406–163)	301 (464–163)
257 (437–180)	225	243 (406–163)
216 (396–180)	181 (406–225)	203 (366–163)
180	163	163

The three almond-pattern frequencies are clearly present in phenyl isothiocyanate together with enough others to account for the other notes in its odour. With acetophenone the authorities differ with regard to certain of the assignments of in-plane and out-of-plane motions. The olfactory evidence, for what it is worth, seems to favour the LeBas assignments.

* Difference frequency.

Table 6 shows the populated, whole-molecule, out-of-plane modes of seven substances the odours of which were presumed not to have a bitter-almond note. The three almond frequencies are, however, prominent in bromo- and iodo-benzene. A number of professional perfumers were asked, therefore, for expert opinions on toluene and on chloro-, bromo- and iodo-benzene with particular reference to any 'nitrobenzene-like' note. They were unanimous that toluene does not have it, but were divided as to the halo-benzenes. Some, but not all, recognized a coarse 'chemical-almond' or 'nitrobenzene-like' note in all three, and especially in iodobenzene. There are not enough frequencies outside the almond pattern to explain why this note should be so heavily overlaid, unless the halo-benzenes lie at an angle to the receptor surface, so that some of their in-plane oscillations (not shown in Table 6) might contribute to the pattern.

Orientation to the receptor probably explains the lack of pronounced odour (apart from trigeminal stimulation)

in phenol and aniline, for these compounds would probably be chemi-sorbed through their reactive substituent groups. Attachment at a point should allow for less vibrational interaction than attachment over an area.

This has been an attempt to find a precise answer to a very precise series of questions which may be summarized thus: (1) What property is common to C_6H_5-CN, C_6H_5-NO_2, and C_6H_5-CHO in addition to their rather similar odours? (2) Is this property found also in C_6H_5-$COCH_3$, C_6H_5-NCS and C_6H_5-I, the odours of which seem to have something in common with the first three? (3) Is this property absent from C_6H_5-CH_3, C_6H_5-OCH_3 and C_6H_5-NH_2, the odours of which are quite different from those of the first three?

In trying to answer these questions, the postulates of the vibrational theory of odour have been spelled out more precisely than ever before, and this can be expected to assist materially in stimulating further tests of the theory.

If difference frequencies do not appear in the spectra, it is not because they have no real existence, but because there is not sufficient anharmonicity to couple the two modes. Without such coupling, radiative transitions are not likely to involve both modes simultaneously. Deformations that accompany collisional excitation make multiple excitation both possible and probable, though subject to limitations from the energy available to excite them. The simultaneous excitation of two normal modes necessarily results in a complex oscillation with a new (difference) frequency. The fact that it may be osmically active without being spectroscopically active suggests that olfactory stimulation does not depend on dipole-dipole coupling. A near-synchronous 'throbbing' of the odorous molecule and the receptor site might, however, permit unusually close approach and allow greater-than-normal electronic (Van der Waals) interactions to establish themselves.

I thank the Canada Department of Agriculture for a grant; and Drs. A. Demerdache, P. N. Daykin, C. Reid and R. E. Burgess for advice.

MOLECULAR DISTRIBUTIONS OF NORMAL FATTY ACIDS AND PARAFFINS IN SOME LOWER CRETACEOUS SEDIMENTS

By KEITH A. KVENVOLDEN
Field Research Laboratory, Socony Mobil Oil Company, Dallas, Texas

SATURATED, straight-chain fatty acids (hereafter called normal fatty acids) and normal paraffin hydrocarbons are common organic constituents of Mowry and Thermopolis shales from the Powder River Basin of Wyoming. This article directs attention to a variety of molecular distributions of normal fatty acids and normal paraffin hydrocarbons observed in a few samples from the shales. The observations provide new evidence for possible relationships between acids and paraffins in sedimentary rocks.

Mowry Shale and Thermopolis Shale are two major shale units in the Lower Cretaceous section of the Powder River Basin. Mowry Shale is dark grey, generally siliceous, and is characterized by the presence of abundant fish scales and thin beds of bentonite. On weathering, Mowry Shale becomes medium-light grey and brittle. The formation ranges in thickness in the basin from 150 to almost 500 ft. Mowry Shale can be usually recognized in the field as a prominent, pine-covered hogback. Thermopolis Shale is soft and greyish black. At the surface, this unit forms grass-covered valleys between sandstone ridges. Exposures are generally poor. The thickness of the Thermopolis Shale varies from 125 to 250 ft. A sandstone is often present between Mowry Shale and underlying Thermopolis Shale.

Four samples of shale will be considered. Two samples of Mowry Shale were obtained from outcrops near Upton and Douglas. Two samples of Thermopolis Shale came from outcrops near Casper and Kaycee. Fig. 1 shows sample locations. Possible effects of surface weathering were kept to a minimum by collecting the samples from pits dug back from the exposed surface. Upton and Casper samples came from road cuts, and Douglas and Kaycee samples came from good, natural exposures.

The presence of acids and paraffins in sedimentary rocks has been noted by previous investigators. Normal fatty acids in rocks have been reported by Cooper[1], Abelson and Parker[2], and Cooper and Bray[3]. Normal paraffins in rocks have been described by Bray and Evans[4,5]. Lawlor and Robinson[6] described both normal fatty acids and normal paraffins in a sample of oil shale from the Green River Formation. These investigators have shown that in sedimentary rocks even-carbon-numbered normal fatty acids dominate odd-carbon-numbered normal fatty acids while normal paraffins usually show a preference for odd-carbon-numbered molecules or nearly equal distributions of odd- and even-carbon-numbered molecules. This report shows not only acid and paraffin distributions similar to distributions noted previously in sedimentary rocks, but also distributions of normal fatty acids with almost equal abundances of even- and odd-carbon-numbered molecules.

Normal fatty acids as well as normal paraffin hydrocarbons containing from about 12 to about 34 carbon atoms per molecule were found in Mowry and Thermopolis shales. Distributions of acids and paraffins from four samples are shown in Fig. 2 where the percentage of each acid (solid line) based on total acids recovered and the percentage of each paraffin (dotted line) based on total paraffins recovered is plotted against the appropriate carbon number. Carbon numbers for acids are shown at the top of the illustrations, and carbon numbers for

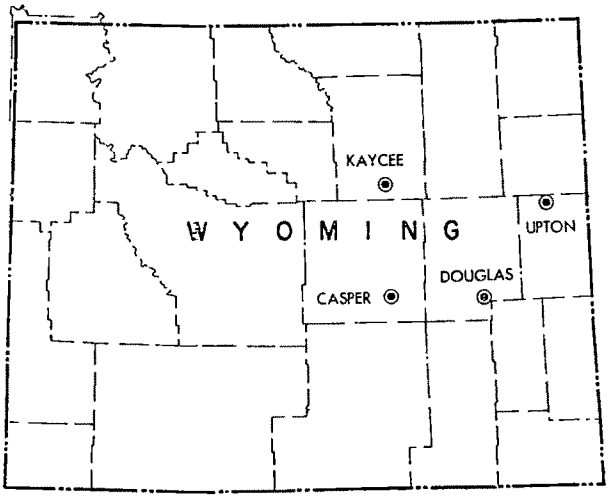

Fig. 1. Location map showing four localities

paraffins are shown at the bottom. Carbon numbers for an acid and a paraffin on the same vertical line are different by one: the acid carbon number is always one larger than the paraffin carbon number.

Relative molecular distributions of acids and paraffins can be characterized by distribution indices. A measure of relative distributions of normal paraffins was defined by Bray and Evans[4] as the mean of two ratios which are determined by dividing the sum of concentrations of odd-carbon-numbered normal paraffins by the sum of even-carbon-numbered normal paraffins over given carbon-number ranges. This measure of the relative abundance of odd- and even-carbon-numbered normal paraffins was called a carbon preference index (CPI)[3]. The relative distribution of normal fatty acids can also be described by a carbon preference index which is defined here as the mean of two ratios which are determined by dividing the sum of concentrations of even-carbon-numbered normal fatty acids by the sum of odd-carbon-numbered normal fatty acids over given carbon-number ranges. To distinguish between distributions of paraffins and acids, CPI_P will represent the carbon preference index for normal paraffins, and CPI_A will represent the carbon preference index for normal fatty acids. Fig. 3 shows formulae for calculating CPI_P and CPI_A. A CPI_P greater than one indicates that odd-carbon-numbered paraffins are more abundant than even-carbon-numbered paraffins. On the other hand, a CPI_A greater than one indicates that even-carbon-numbered acids are more abundant than odd-carbon-numbered acids. CPI_P and CPI_A values equal to one indicate that paraffins or acids have equal abundances of even- and odd-carbon-numbered molecules. Limits used in computing CPI_P and CPI_A are arbitrary. In this study fractionation of both paraffin and acid molecules containing less than about 16 carbon atoms is severe due to the analytical method used. Therefore, the lower limit for computation of CPI_P is C_{16} and of CPI_A is C_{17}. Upper limits for computation are C_{32} for paraffins and C_{33} for acids. Concentrations of molecules having more carbon atoms are low and approach the limits of detection of the analytical method.

$$CPI_P = 1/2\left(\frac{\Sigma \text{ odd-carbon paraffins from } C_{17} \text{ to } C_{31}}{\Sigma \text{ even-carbon paraffins from } C_{16} \text{ to } C_{30}} + \frac{\Sigma \text{ odd-carbon paraffins from } C_{17} \text{ to } C_{31}}{\Sigma \text{ even-carbon paraffins from } C_{18} \text{ to } C_{32}}\right)$$

$$CPI_A = 1/2\left(\frac{\Sigma \text{ even-carbon acids from } C_{18} \text{ to } C_{32}}{\Sigma \text{ odd-carbon acids from } C_{17} \text{ to } C_{31}} + \frac{\Sigma \text{ even-carbon acids from } C_{18} \text{ to } C_{32}}{\Sigma \text{ odd-carbon acids from } C_{19} \text{ to } C_{33}}\right)$$

Fig. 3. Formulae for calculating the carbon preference index for normal paraffin hydrocarbons and for normal fatty acids

Fig. 2 (upper left) shows the distributions of acids and paraffins recovered from a sample of Mowry Shale from near Upton. CPI_A is 2·49 and CPI_P is 1·63. Acids show an even-carbon preference, and paraffins show an odd-carbon preference. Another type of distribution of acids and paraffins from Mowry Shale is shown in Fig. 2 (lower left) for a sample from south of Douglas. Both CPI_A and CPI_P are near 1·00 (1·05 and 1·10). Little preference for either even-carbon-numbered acids or odd-carbon-numbered paraffins is observed. A sample of Thermopolis Shale from south-west of Casper, shown in Fig. 2 (upper

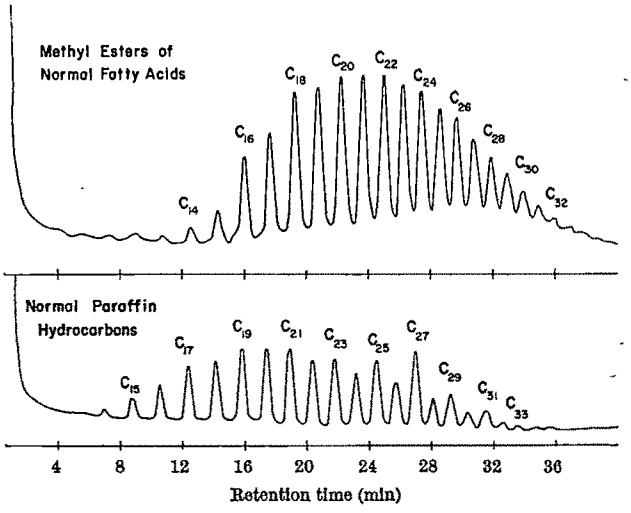

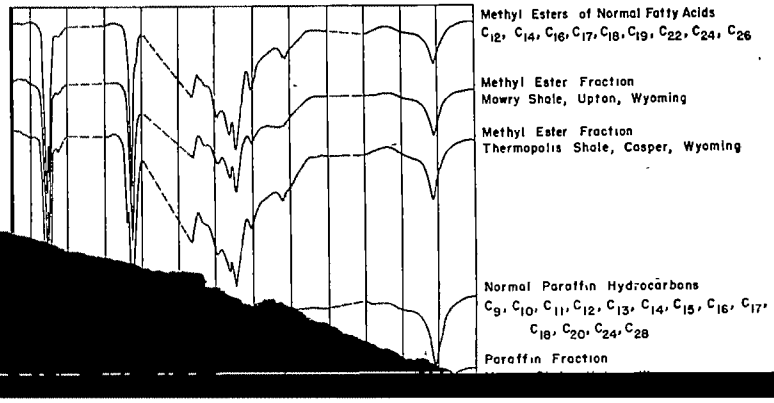

Fig. 4. Gas chromatograms of methyl esters of normal fatty acids and normal paraffin hydrocarbons in a sample of Thermopolis Shale from near Casper, Wyoming. F and M Model 500 gas chromatograph, 24 in. by 0·25 in. column packed with 0·5 per cent silicone grease (*DC*–11) on 60–80 mesh glass beads; temperature programmed from 75° C to 300° C at 5·6° C/min

right), contains acids equally distributed between molecules having even and odd numbers of carbon atoms (CPI_A is 1·05). Paraffins, however, have a definite preference for odd-carbon-numbered molecules (CPI_P is 1·31). Acids shown in Fig. 2 (lower right) from Thermopolis Shale near Kaycee show a distinct even-carbon preference (CPI_A is 1·32), and at the same time paraffins show a definite odd-carbon preference (CPI_P is 1·43). For any given sample the general trends of the molecular weight distributions are remarkably similar.

The analytical procedure used to isolate normal fatty acids and normal paraffin hydrocarbons is a modification of one used by Cooper[3] for isolation of fatty acids. Acids and paraffins were obtained from dried, crushed sediments by extraction with a solution of potassium hydroxide in methanol. Free acids, salts of acids, and acids combined as esters were probably recovered by this method. Some of the acids may have been derived from complex polymeric materials commonly called 'kerogen'. Acids and paraffins were extracted from the saponification mixture after acidification. Acids were converted to methyl esters. Normal fatty acid methyl esters and normal paraffins were separated from other lipid material by urea adduction. Acids were separated from paraffins by silica-gel chromatography. Identification of normal fatty acids as methyl esters and nor… raffin hydrocarbons was based o… procedure, infra-red and… and gas chromatogr… centrations of a… calculated fr… tograms… sh…

Infra-red spectrometry established the presence of methyl esters of fatty acids and normal paraffins in fractions obtained from silica-gel chromatography. Fig. 5 shows infra-red spectra of fractions from the Mowry Shale sample collected near Upton and the Thermopolis Shale sample collected near Casper. These spectra are compared with spectra obtained from standard solutions, one containing a mixture of methyl esters of normal fatty acids and the other containing a mixture of normal paraffin hydrocarbons. Spectra of ester fractions from the shales are very similar to the spectrum of the solution containing a known mixture of methyl esters of normal fatty acids as seen at the top of Fig. 5. At the lower part of Fig. 5 spectra of paraffin fractions from the shales compare favourably with the spectrum obtained from the known mixture of normal paraffins. Spectra of methyl ester and paraffin fractions show strong absorption bands in the 3·4–3·5μ region, indicating the presence of methyl and methylene groups, and a band at 13·9μ, indicating methylene chains with four or more carbon atoms. Spectra of methyl ester fractions have an ester carbonyl adsorption band at 5·75μ and a triplet pattern with adsorptions at about 8·0, 8·3 and 8·5μ which are characteristic of methyl esters of long-chain fatty acids[7].

Each mass spectral analysis of chromatographic fractions containing methyl esters of normal fatty acids as determined by gas chromatography and infra-red spectrometry showed a base peak at *m/e* 74. This peak is the base peak for methyl esters of higher normal fatty acids[8]. Parent peaks were present at *m/e* values equal to those of methyl esters of normal fatty acids (. . . 326, 340, 354, 368, 382 . . .). Mass spectral and gas chromatographic data for methyl esters of normal fatty acids in the Mowry Shale sample from near Upton and the Thermopolis Shale sample from near Casper are shown in Fig. 6. Parent-peak heights from mass spectra are compared with peak heights from gas chromatograms. Peaks at C_{18} and C_{26} are enhanced because of the presence of internal standards. Comparison of mass spectral and gas chromatographic data for methyl esters of normal fatty acids in these samples shows a parallelism between ester distributions given by parent–mass peaks and gas chromatographic peak heights. Mass spectral data confirm the presence and distribution of normal fatty acid esters as established by gas chromatography.

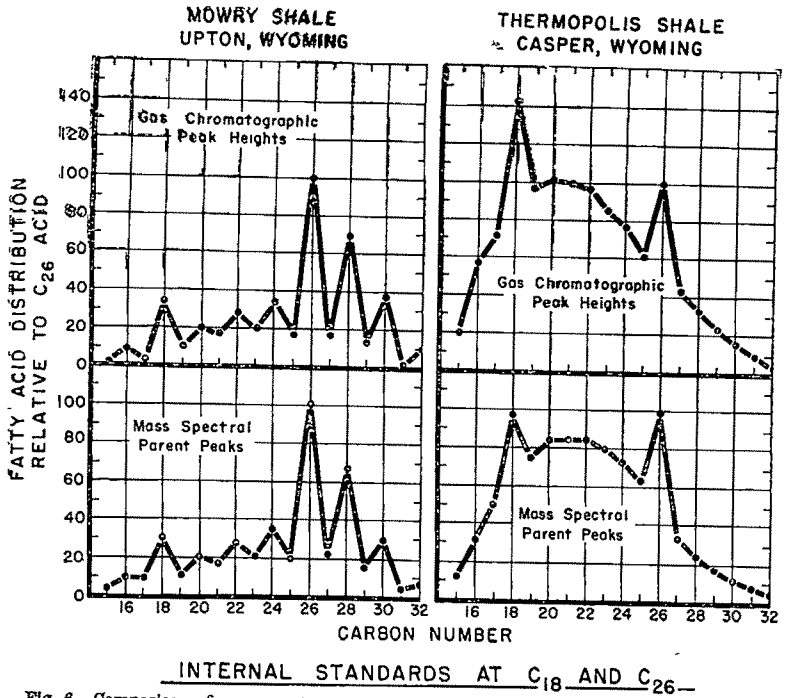

Fig. 6. Comparison of mass spectral and gas chromatographic analyses of methyl esters of normal fatty acids in Mowry and Thermopolis Shales

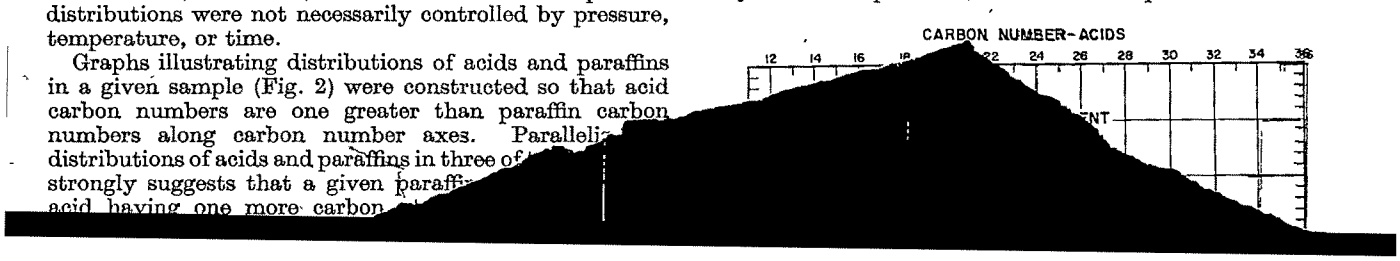

One result of this investigation is the observation that distributions of normal fatty acids as well as normal paraffin hydrocarbons can be different in similar lithologies of the same geological unit. For example, one Mowry sample has a CPI_A of 2·49 while the other has a CPI_A of 1·05. Respective CPI_Ps are 1·63 and 1·10. Thermopolis samples also have contrasting CPI_A values of 1·32 and 1·05. Distributions of paraffins in the Thermopolis samples differ little with CPI_Ps of 1·43 and 1·31. Different CPI_As and CPI_Ps in the same rock units suggest that factors controlling the distributions of acids and paraffins are not necessarily reflected in the gross lithology. Original distributions of acids and paraffins may have been different at various places in time intervals represented by a given lithology, or environments for chemical changes may have been more favourable or less favourable at various localities. All four samples experienced about the same pressures and temperatures for approximately the same time, because these samples are from outcrops of about the same geological age on the rim of the Powder River Basin; therefore, differences in acid and paraffin distributions were not necessarily controlled by pressure, temperature, or time.

Graphs illustrating distributions of acids and paraffins in a given sample (Fig. 2) were constructed so that acid carbon numbers are one greater than paraffin carbon numbers along carbon number axes. Parallel distributions of acids and paraffins in three of strongly suggests that a given paraffi acid having one more carbon

likely to be attacked. Furthermore, the rate of oxidation of any oxidation product would probably exceed the rate of oxidation of the paraffin.

Distributions of normal fatty acids and normal paraffins in these Lower Cretaceous sediments contrast greatly with distributions of acids and paraffins in a modern sediment. Fig. 7 shows normal fatty acids and normal paraffins in a modern sediment from San Nicolas Basin off the coast of southern California. CPI_A is 7·06 and CPI_P is 4·85. Large CPI_As and CPI_P values can be expected in most modern sediments because of the ubiquity of even-carbon-numbered normal fatty acids and odd-carbon-numbered normal paraffins in biological systems. Not only are carbon preference index values for acids and paraffins much larger in the modern sediment than in the ancient sediments, but also general trends of the molecular weight distributions of acids and paraffins in the modern sediment are not similar as they are in the ancient sediments. If, in the modern sediment, normal paraffins were derived directly from normal fatty acids, the relative percentage of C_{15}-paraffin especially and also C_{25}- and C_{23}-paraffins should have been larger. At the same time the relative percentages of C_{30}-, C_{32}- and C_{34}-acids should have been larger to provide for paraffins at C_{29}, C_{31} and C_{33}. These observations suggest that acids and paraffins in the modern sediment are not related, at least not in the same way as are acids and paraffins in the ancient sediments.

If in Thermopolis or Mowry time original distributions of normal fatty acids and normal paraffins were somewhat similar to distributions found at present in a modern sediment, observed acid–paraffin distributions, especially for molecules larger than C_{20}, in the Lower Cretaceous rocks can generally be explained by schemes involving originally deposited fatty acids and normal paraffins as starting materials. In a scheme proposed by Cooper[1] step-by-step decarboxylation of fatty acids occurs forming alkyl radical intermediates which react to give normal paraffins with one less carbon atom and fatty acids with one less carbon atom than the parent acids. Newly generated fatty acids react in the same manner as original acids. Operation of this scheme on originally deposited fatty acids, under conditions favouring formation of more fatty acids than paraffins, reduces carbon preference index

values for both fatty acids and paraffins. As a consequence of Cooper's scheme absolute concentrations of fatty acids should decrease while normal paraffins formed from acids should accumulate with initially deposited normal paraffins. Detailed mechanisms of chemical reactions which may take place in sediments to account for various acid–paraffin distributions are not known. Free radical as well as other kinds of reactions should be considered. Normal paraffins from other sources such as kerogen are possible, but parallelism of distributions of normal fatty acids and normal paraffins in the Lower Cretaceous sediments seems to indicate that a major source of normal paraffins could be normal fatty acids. The total concentrations of acids and paraffins in the examined samples (Table 1) suggest that in initially deposited sediments sufficient normal fatty acids can be present to provide normal paraffins which can modify the distribution of originally deposited normal paraffin hydrocarbons.

Table 1. Concentrations of Normal Fatty Acids and Normal Paraffin Hydrocarbons Recovered from Sediments

	Normal fatty acids (μmol/kg)	Normal paraffin hydrocarbons (μmol/kg)
Modern sediment, San Nicolas Basin	132·0	5·9
Mowry Shale, Upton, Wyoming	9·9	5·2
Mowry Shale, Douglas, Wyoming	97·7	113
Thermopolis Shale, Casper, Wyoming	22·0	6·9
Thermopolis Shale, Kaycee, Wyoming	27·4	3·7

The various molecular distributions of fatty acids and normal paraffins in the Lower Cretaceous sediments (Fig. 2) can be interpreted in light of the proposed scheme for obtaining paraffins from fatty acids. Fatty acids in the Thermopolis sample from near Casper and the Mowry sample from near Douglas have degraded to such an extent that they have lost most of the even-carbon preference they may have had initially. Paraffins in the Douglas sample have lost most of the odd-carbon preference they may have had originally, but paraffins at the Casper locality still have a distinct odd-carbon preference. At the Casper locality initial sediments may have had an unusually high concentration of odd-carbon-numbered normal paraffins relative to even-carbon-numbered normal fatty acids. Paraffins generated from acids have been unable to swamp-out the odd-carbon preference at the Casper locality. The slight preference for C_{27}, C_{29}, C_{31} and C_{33} normal paraffins in the Douglas sample is probably a reflexion of initially deposited normal paraffins. Fatty acids from the Upton and Kaycee samples appear to be less degraded than fatty acids from the Douglas and Casper samples. The reason for this may be due to higher initial CPI_A values for acids in the sediments from Upton and Kaycee localities or due to more favourable environments for degradation in the sediments from Casper and Douglas localities.

Various distributions of acids and paraffins in sediments may reflect different degrees of maturation in the paraffin-forming process of petroleum generation. Normal paraffins in petroleum usually have almost equal abundances of odd- and even-carbon-numbered molecules[5]. In any petroleum generation scheme final normal paraffins, therefore, must have a CPI_P near 1·0. In this investigation a CPI_P near 5·0 was determined for normal paraffins in a modern sediment. Normal paraffins of the ancient sediments had CPI_P values ranging from 1·63 to 1·10. The final CPI_P value approaches values found for paraffin distributions in crude oils of the Lower Cretaceous section of the Powder River Basin. At the same time, a reduction of CPI_A values is observed going from the modern sediment with a CPI_A near 7·0 to the ancient sediments where values ranged from 2·49 to 1·05. Although no report is known of normal fatty acids in crude oils of the Lower Cretaceous, small concentrations of normal fatty acids (from C_8 to C_{18}) have been found in a California petroleum[9]. These normal fatty acids have only a slight predominance of even-carbon-numbered molecules over odd-carbon-numbered molecules. The paraffin-forming process of petroleum generation, therefore, probably involves maturation in which distributions of normal paraffins approach equal abundances of odd- and even-carbon-numbered molecules as a result of degradations of normal fatty acids which produce distributions of fatty acids with nearly equal abundances of even- and odd-carbon-numbered molecules.

Molecular distributions of normal fatty acids and normal paraffin hydrocarbons in these Lower Cretaceous sediments suggest that many of the normal paraffins now found in these sediments could have come about through transformations of normal fatty acids involving loss of carbon and oxygen atoms. Specific reactions for fatty acid transformations in sediments are not known. It is likely that different degrees of degradation, suggested by the samples, of normal fatty acids to lower-carbon-number normal paraffins and normal fatty acids reflect different initial acid–paraffin distributions and different local chemical environments for degradation. Acid–paraffin distributions in sediments may reflect degrees of maturation in the paraffin-forming process of petroleum generation.

I thank J. E. Cooper, whose original investigations form the foundation of this work; J. T. Wall, who did the laboratory work; and D. F. Cardinal for advice and co-operation in selecting and collecting samples.

EVIDENCE FO[redacted]FIBRE' ORGANIZATION IN

somes occurs by a tight but irregular folding of the interphase fibres into compact metaphase 'packages'. At least two corollaries are implicit in this hypothesis: (1) metaphase and anaphase chromatids are not expected to contain pairs of half-chromatids; (2) gross coiling, as observed in large chromosomes by light microscopy, is regarded as quaternary structure which is absent in small chromosomes and which, when it occurs, is superimposed on a fundamental, folded fibre structure. This article reports recent comparative observations made with larger chromosomes prepared from human cells by the same techniques previously used to investigate the honeybee chromosomes; these observations, for the most part, confirm the expectations of the folded-fibre model and support its applicability to chromosomes in general.

Two sources were used to obtain human chromosomes: (1) 3-day cultures of peripheral leucocytes in which the blood cells were donated by laboratory personnel and incubated according to the techniques of Moorhead *et al.*[3] (including an important modification by Dr. H. D. Moon[4], which requires only three drops of blood from a finger tip); (2) a commercial line of human liver cells (Microbiological Associates, Albany, California), which were subcultured according to the Chang technique[5] and incubated for 2 days before further treatment. Both blood and liver cells were prepared for the electron microscope in the same way: first, abundant metaphases were obtained by incubating the cells with colchicine for 12–18 h; the cells were then lysed in hypotonic medium (usually distilled water), floated on the clean surface of a trough filled with distilled water, and picked up directly on 'Formvar'-coated grids; after the grids had been dehydrated through an ordinary series of ethanol dilutions, they were passed from absolute alcohol into amyl acetate and finally dried by the critical point method of Anderson[6]. Fixation and staining, as well as sectioning, were omitted in most instances. Electron micrographs were made as a through-focus series with an RCA *EMU-3G* after careful normalization of the lenses.

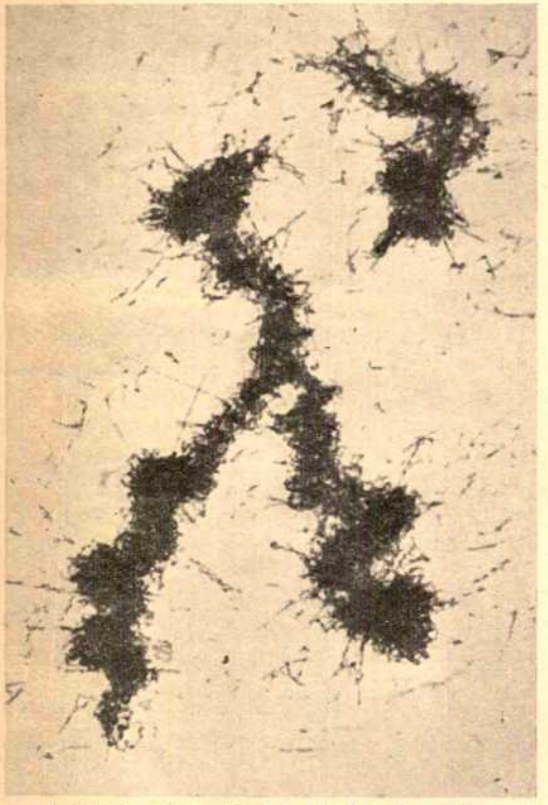

Fig. 1. A metaphase chromatid pair isolated from human liver culture cells. Note the apparent quaternary coiling which is superimposed on a basic, folded-fibre structure. The broken ends of three fibres protrude from the stump of the fractured arm (× *c.* 16,470)

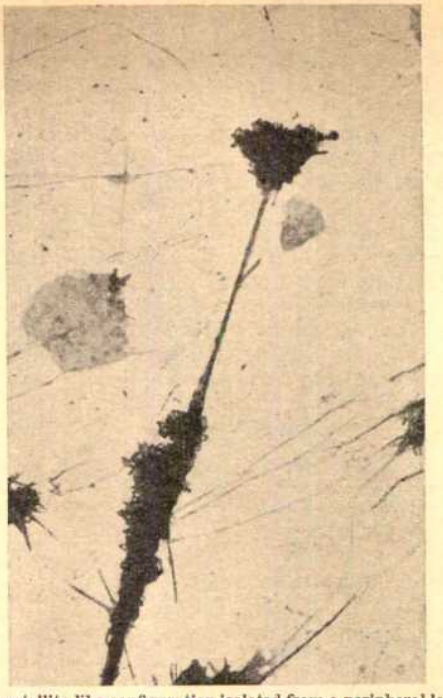

Fig. 3. A satellite-like configuration isolated from a peripheral leucocyte culture. In the connecting strand, three lengths of fibre lie side by side (one of which has broken) (× *c.* 6,990)

Grids prepared in this way usually contain one to three separate groups of metaphase chromosomes, in addition to varying numbers of interphase nuclei. No one group of chromosomes includes the complete karyotype, and often the same group contains some chromosomes which are well preserved, others which are less well preserved, and still others which lie across one another or tangled together in ways that make them unsuitable for investigation. Although the same effects are found in light microscope preparations, the much greater abundance of material there makes it possible to select complete, well-spread plates for karyotype examinations. Unfortunately, the relative scarcity of material with present electron micro- [illegible] has thus far made karyotype analysis [illegible]eless, the fine structure of individual [illegible]ely accessible by present methods. [illegible] that the familiar morphology of [illegible] is preserved by the tech- [illegible]hology (like that of

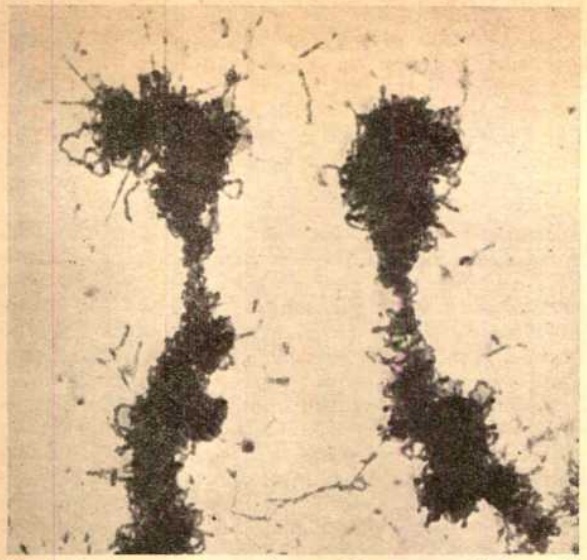

Fig. 4. Centromere regions and arms of two separated chromatids isolated from human liver culture cells. Note that the centromere fibres appear to be continuous with the chromatin fibres of the arms and resemble them in appearance. Some apparent quaternary coiling is also visible in the arms (× *c.* 17,690)

indicates that these vary around 230 Å at interphase and have a somewhat greater dimension (possibly exceeding 300 Å) at metaphase. The fibres have never been observed to form orderly rope-like complexes by winding together in pairs. Furthermore, human chromatids, like those of honeybees, lack any visible, paired half-chromatid structure.

On the other hand, the larger human chromosomes differ notably from honeybee chromosomes in showing clear evidence of quaternary coiling. This is especially conspicuous in Fig. 1, where the uncoiled portions of the chromatid arms (near the centromere) show a folded-fibre structure and diameters in the order of 0·3μ, whereas the coiled regions have apparent diameters exceeding 0·6μ and are very electron dense (an effect which is expected because of their greater thickness). Fig. 2 interprets this structure for a single chromatid, which is considered to have condensed first by an irregular folding of one or several 230 Å fibres, and thereafter by gross left- or right-handed coiling of the rod-form produced in the first phase.

In the intact chromosome the intricacy of three-dimensional folding usually makes it impossible to trace a given fibre for more than a short distance; nevertheless, significant clues regarding the arrangement of fibres within each chromatid have been found. For example, Fig. 3 illustrates a satellite-like configuration (either a natural satellite[7] or an accidentally-stretched chromatid arm), in which two separate, light-resolvable segments of the chromatid are connected by a narrow neck of unfolded fibres. The connecting strand, which would be invisible with the light microscope, appears to contain three parallel fibres (one of which has broken) and its continuous length is more than 4μ. In Fig. 1, three broken fibre ends can also be discerned protruding from the stem of the single broken chromatid arm. In Fig. 4 the diameter of each chromatid at its centromere actually falls below the limit of light resolution, and in this instance also the chromosome arms are seen to be connected by approximately three fibres. It is clear in Figs. 1 and 4, at least, that the centromere regions of human chromosomes are composed of fibres morphologically identical with the fibres of the arms, and that these centromere fibres are continuous with the arm fibres. Since some of the special properties of the centromere as observed in light microscopy (for example, reluctance to stain) may be accounted for merely by the difficulty in resolving the chromatid body at this point, there may be no real difference between centromere fibres and 'true' chromatin fibres.

On the other hand, it has not yet been determined how the centromere is organized to hold together the chromatids at metaphase and then to release them at anaphase. Originally it was suggested that, in a folded-fibre chromosome, the central, unreplicated portion of each chromosome might serve to hold together the previously replicated arms[2]; such a mechanism would not be inconsistent with the appearance of the centromere in chromosomes such as that illustrated in Fig. 1. However, most chromosomes resemble that shown in Fig. 5, where it is apparent that at least part of the centromere region has already been duplicated before the chromatids separate. In this bivalent the chromatids are held together at two points, and in the centromere proper, multiple lengths of fibre (about fifteen) pass from one chromatid to the other. Although it is not difficult to devise patterns of folding which can account for such chromatid pairs without violating the restrictions of a folded-fibre model, this question of centromere structure requires further investigation.

With respect to the number of separate fibres that are present in any given chromatid, there are also several possibilities open. As indicated in Figs. 1, 3 and 4, the narrowest chromatid regions observed so far still contain about three lengths of fibre lying side by side; nevertheless, all these lengths of fibre might actually be continuous with one another at the ends of the chromosome or elsewhere. Several possible patterns of folding for a very long, single fibre are illustrated in Fig. 6. In chromatid *A* the fibre is folded transversely along its entire length, in chromatid *B* it is folded longitudinally, and in chromatid *C* there is a complex combination of transverse and longitudinal folding. For most of the regions in chromatid *C*, stretching would seem to reveal three lengths of fibre lying side by side; a break in any one of these fibre lengths would very likely appear in the light microscope as a 'half-chromatid' break; yet this chromatid really contains only a single continuous fibre.

Some insight regarding the problem of chromatid 'strandedness' can be obtained by comparing the estimated total length of 230 Å fibre in a specific chromatid with the theoretical length of DNA present in the same chromatid. For example, in Fig. 1, one chromatid has a length of 4·9μ, a diameter of 0·6μ, and on a volume basis could contain approximately 3,330μ of fibre (assuming the volumes of cylinders). From its dimensions this chromosome is likely to represent one of the 6-*X*-12 group, in which case the measurements of Rudkin *et al.*[8] would

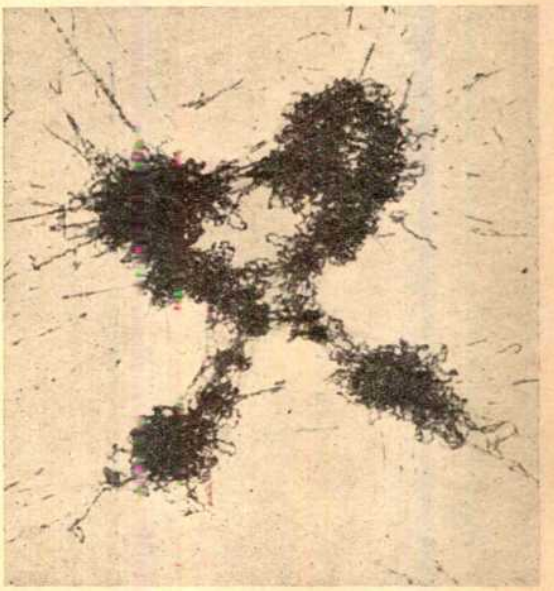

Fig. 5. A metaphase chromatid pair isolated from human liver culture cells. In the centromere region, multiple lengths of fibre pass from one chromatid to the other (× *c.* 14,270)

indicate that each chromatid contains 2·45 per cent of the diploid DNA content. Calculated from a total diploid DNA content equivalent to 180 cm of Watson–Crick molecule[2], this chromatid would then contain 4·4 cm of DNA, and the ratio of DNA length to fibre length would be about 13 : 1. Similar calculations for one of the tiny chromatids of the 21–22 group (having approximately the volume of a 1μ sphere) have yielded a ratio in the order of 9 : 1. The fact that these chromatids contain some ten times as great a length of Watson–Crick DNA molecule as of 230 Å fibre makes it less likely (though not impossible) that the apparent three-strandedness of the chromatids in Figs. 1, 3 and 4 represents a simple polytenic organization. Even if the side-by-side lengths of fibre were polytenic replicates, it would still be necessary to postulate either: (1) that each 230 Å fibre contains about ten DNA molecules lying side by side; or (2) that each fibre contains one DNA molecule which is coiled in a 10 : 1 secondary helix (as postulated in the folded-fibre model). In any event, the presence of only three strands fits better with the model illustrated in Fig. 6*C* than with a scheme for four-ply polyteny (though a fourth strand could easily be overlooked).

While it is true that the electron micrographs alone do not permit firm conclusions about chromatid strandedness, a somewhat clearer picture emerges if the fine structure is considered in relation to various recent experimental analyses. For example, autoradiography of human cancer tissue (HeLa) after exposure to tritiated thymidine has shown that replication of entire human chromosomes is semi-conservative[9], just as replication of individual DNA molecules is semi-conservative. A consequence of this fact is that each chromatid must possess two DNA-containing units which extend the length of the chromatid and which retain their structural integrity from one mitosis to the next. However, no such duplex units are visible in electron micrographs (for example, Figs. 1, 3, 4 and 5), either at the level of 230 Å fibres or at higher dimensions. This discovery supports Taylor's interpretation that the two units are the two polynucleotide chains of one or many (linked) DNA molecules, which in all probability form the cores of the 230 Å fibres[1]. If it is really true that duplex structural units larger than the 230 Å fibres do not exist within the chromatid, then it is difficult to understand how the side-by-side fibres could be polytenic replicates, or even separate fibres, while the chromatid as a whole continues to show semi-conservative replication. The only model that seems able to account for all these relationships simultaneously is that based on a single, long folded fibre.

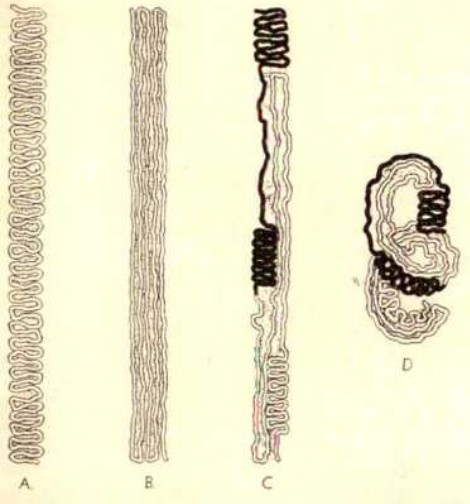

Fig. 6. Possible patterns of folding for a single, long chromatin fibre. (*A*) Transverse folding; (*B*) longitudinal folding; (*C*) combined transverse and longitudinal folding; (*D*) quaternary coiling superimposed on chromatid *C*. For further explanation refer to text

Recently, Solari[10] has confirmed the existence of single, long DNA molecules in higher organisms. In an electron microscope investigation of surface-spread sea-urchin sperm, he found that the DNA of these organisms occurs in the form of chromatin fibrils at least 50–93μ long. It would seem that the great length of these DNA strands must rule out general models of chromosome structure which postulate many short DNA segments in each chromatid (for example, Taylor's 'ladder' model[11]), and it makes unlikely those models which view the chromosome as a rope-like structure composed of parallel polytenic strands.

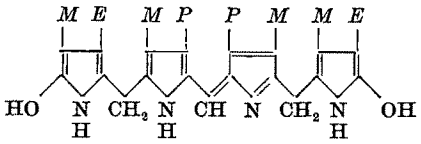
Evidence concerning the dimensions of interphase chromatids has been obtained by Neary *et al.*[12], using the chromosomes of *Tradescantia* (which are also known to replicate semi-conservatively[9]). Contrary to the results of earlier workers, these investigators found that chromatid breaks and exchanges are produced in efficient yield by low-energy, monochromatic X-rays, the photoelectrons of which have integrated path lengths of about 500 Å. Although their data can be interpreted on the basis of several models, one suggestion is that "the interphase chromatid diameter is less than half the range of (0·05μ) . . .". This would correspond rather closely to the dimension of a single 230 Å fibre, and would tend to support a folded-fibre model of chromosome structure.

Still another recent experimental investigation, which seems to provide striking support for a folded-fibre model, has been reported with synchronously dividing cells of the smut fungus, *Ustilago*[13]. The frequency of mitotic crossing-over in these cells can be increased by irradiation with ultra-violet light, and in synchronized cells this effect can be investigated at different times during the cycle of DNA synthesis. Holliday has found that, depending on the time of irradiation, crossing-over is induced between different genetic markers; of even greater significance, it appears that genes near the ends of the chromosome arms are affected earlier than genes positioned nearer the centromeres. These results strongly suggest that in *Ustilago* a telomere-to-centromere pattern of chromosome replication occurs, as postulated in the folded-fibre model[2].

An apparently sequential telomere-to-centromere pattern of DNA synthesis has also been detected in several types of plant and animal chromosome by autoradiography (see discussion in ref. 2). However, many other types of chromosome show patterns of incorporation which are complex and apparently irregular. That such irregular metaphase patterns do not necessarily imply an irregular interphase replication is illustrated in Fig. 6. The dark length of fibre in Fig. 6*C* shows a possible pattern of sequential incorporation as it would appear in a relatively extended folded-fibre chromatid. By contrast, Fig. 6*D* shows the same chromatid after it has gone through a process of quaternary coiling; though the sequence of incorporation is the same, the autoradiograph pattern would be entirely altered, possibly giving no hint of sequence at all. If a monomolecular connecting strand should occur (as in Fig. 6*C*), the presence of labelled thymidine in that part of the chromatid might easily go undetected by some autoradiograph techniques, and the appearance would then be of two separate loci synthesizing DNA simultaneously. Such patterns have been reported, but a much more sensitive technique of 'replicate autoradiography', recently introduced by Stubblefield[14], has revealed that chromatid loci of high specific activity are often connected by intermediate areas of lower specific activity.

The apparent folded-fibre organization of human chromosomes reported in this article, together with recent experimental investigations cited from other laboratories, would seem to extend the usefulness of the folded-fibre model well beyond the genetic material of honeybee embryos, where it was originally inferred. Although major problems, such as the organization of the centromere and the mechanism of replication in very long DNA

molecules, still remain to be clarified, essentially these same problems exist for any valid theory of chromosome structure. That DNA molecules many hundreds of microns long do replicate sequentially has been shown in micro-organisms by Cairns[15]; only further research can reveal the mechanism of this replication, which very probably occurs in the chromosomes of higher organisms as well. It is interesting to estimate that, if the folded-fibre model is correct, the average rate of DNA replication in cultured human leucocytes is about 27μ per min per replication site (based on diploid nuclei containing 180 cm of DNA[2], 46 chromosomes, two replication sites per chromosome, and a minimum DNA synthesis period of 12 h[16]). Although this result is only approximate, it is in good correspondence with Cairns's estimate of 20–30μ per min for the single replication fork of *E. coli*[15].



I thank Mr. Richard Jahn and Mr. Peter Rae for their assistance, and Mrs. Patricia Levy for drawing Figs. 2 and 6. This work has been supported by National Science Foundation grant *GB*–1924. A preliminary abstract has been published[17].

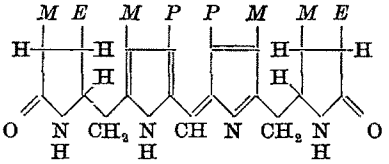
MOLECULAR SPECIES OF THE UROBILINS

By Dr. A. H. JACKSON and K. M. SMITH
The Robert Robinson Laboratories, University of Liverpool
AND
Prof. C. H. GRAY and Dr. D. C. NICHOLSON
Department of Chemical Pathology, King's College Hospital Medical School

THE urobilins are dipyrrylmethene compounds joined at the two α-pyrrolyl positions by way of methylene bridges to either pyrrolenone or pyrrolidone rings[1]. An optically inactive urobilin, usually designated *i*-urobilin or urobilin IXα, is formed by the dehydrogenation of mesobilirubinogen, the octahydrogenated product formed from bilirubin on reduction with sodium amalgam[2]. Urobilin IXα was synthesized by Siedel[3] and shown to have the structure (I) although subsequently the *bis*lactam structure (II)[1] has been accepted as more probable[4]. An inactive urobilin believed to be identical with urobilin IXα has been isolated from faeces[5].

(I)



(II)

$M = CH_3$; $E = C_2H_5$; $P = CH_2CH_2COOH$

Stercobilin is readily isolated from normal faeces, in which it occurs as stercobilinogen[5]. The latter is a dihydrogenated colourless precursor formed by the bacterial reduction of bilirubin or bilirubin glucuronide in the intestines. Stercobilin is strongly laevorotatory[5], resists racemization even in concentrated hot alkali[6], and elementary analysis[7] suggests that its molecule contains four hydrogen atoms more than that of urobilin IXα. The products of degradation of stercobilin[1] suggest that it has the structure (III) which represents a compound also obtained by the extensive catalytic reduction of bilirubin[8].

A third pigment, *d*-urobilin, may be isolated from the faeces of subjects receiving broad-spectrum antibiotics[9]. This compound, which has an even greater optical activity than stercobilin, is dextrorotatory and contains two hydrogen atoms less per molecule than urobilin IXα. The site of the resulting extra unsaturation in *d*-urobilin has not been unequivocally located, but is probably present in a vinyl group attached to one end ring[1]. *d*-Urobilin is readily racemized in alkali[1] presumably with production of a laevorotatory enantiomorph, although the latter has never been isolated.

(III)

The chromogen obtained by the tetrahydrogenation of *d*-urobilin affords, on oxidation, a further urobilin, apparently isomeric with urobilin IXα: this product has been called *d*-urobilin IXα because, while it resembles urobilin IXα in containing only one readily reducible double bond, it has a *d*-rotation similar in magnitude to that of *d*-urobilin[1].

The possibility that mass spectrometry might throw light on the structure of these compounds led us to undertake their systematic investigation. The detailed structures of the various fragments are still being investigated and will be the subject of a separate report; the preliminary assessments of the molecular weights of the parent compounds may well demand revision of the present ideas of the structures of the urobilins.

Mass spectrometric studies were made in the A.E.I. '*MS* 9' mass spectrometer equipped with direct inlet and operating at temperatures up to 250°. Stercobilin hydrochloride was isolated from normal faeces by the method of Watson[5] and after successive recrystallization from chloroform had $[M]_D^{CHCl_3}$ $-24{\cdot}8° \times 10^3$ ε $93{\cdot}0 \times 10^3$ at 496 mμ. *d*-Urobilin hydrochloride, $[M]_D^{CHCl_3}$ $+27{\cdot}6° \times 10^3$ ε $93{\cdot}0 \times 10^3$ at 499 mμ, was obtained and purified similarly but with preliminary separation from a little violet pigment

by extraction of the latter from aqueous solution into ether. Faecal urobilin IXα ε $60{\cdot}8 \times 10^3$ at 496 mμ in $CHCl_3$ was obtained from the chloroform mother liquors of the *d*-urobilin preparations, by concentration and precipitation into petroleum spirit. The hydrochloride in chloroform was without optical activity and gave a characteristic violet colour on treatment with warm acidic dioxane[9]. Urobilin IXα was obtained also by the reduction and oxidation of bilirubin again being isolated as the hydrochloride with recrystallization from chloroform–acetone mixture. The product before the final crystallization had ε $61{\cdot}9 \times 10^3$ in chloroform.

The results of mass spectrometry show that bilirubin (Weddel Pharmaceuticals Ltd., ε $66{\cdot}0 \times 10^3$ at 450 mμ in chloroform) consists mainly of a single species of molecular weight 584 in accordance with the accepted structure; this was accompanied by trace amounts of some products of higher hydrogenation, possibly dihydrobilirubin or mesobilirubin. Results with the natural and synthetic urobilins are of particular interest. These, although hitherto regarded as pure compounds having analyses compatible with accepted structures, proved by mass spectrometry to be mixtures.

A specimen of *d*-urobilin isolated by Moscowitz, but of unspecified optical properties, was almost wholly of molecular weight 588 with a small amount of a component of weight 590 (ref. 15). The 588 component is in accordance with the presence of two reducible double bonds per molecule compared with one in urobilin IXα, as found earlier[1]. The *d*-urobilin isolated by us for mass spectrometry also had the compound of molecular weight 588 as the major component, but accompanied by a considerable quantity of pigment of molecular weight 590. The latter, considering the high optical rotation and molecular extinction of the *d*-urobilin, may be considered a *d*-rotatory urobilin, possibly identical with *d*-urobilin IXα[1].

Faecal urobilin IXα unexpectedly contained only a minor fraction of molecular weight 590 corresponding to its accepted structure (II); the major component was of mass 588, possibly identical with *d*-urobilin. On the other hand, the urobilin IXα prepared *in vitro* from bilirubin was mainly of molecular weight 590 in accordance with structure (II), accompanied by small amounts of a component of molecular weight 588. Both faecal urobilin IXα and that obtained from bilirubin contained a component of molecular weight 592. The *in vitro* product contained about 20 per cent of this, but the component may well have constituted about 50 per cent of the faecal urobilin IXα. The presence of this in the natural pigment is of particular interest; it represents a dihydro-urobilin IXα never before isolated or detected and intermediate between the structure formerly accepted for urobilin IXα (II) and stercobilin (III).

Stercobilin contained very little of a component of molecular weight 594 as required by the structure III. It consisted instead of two components, one of which was stable and of molecular weight 592. It is not at all certain that the 592 component is identical in stercobilin and urobilin IXα. An intermediate of this molecular weight between structures (II) and (III) would probably be readily oxidized to a violin. Urobilin IXα is oxidized in this way by ferric chloride, but stercobilin is quite unaffected. Either the 592 component in stercobilin differs from that in urobilin IXα or is stabilized by some peculiarity of molecular association. The second component of stercobilin was heat labile with a molecular weight 596, incompatible with any structure yet postulated for a urobilin. Stercobilin resembles *d*-urobilin and cryptopyrrolemethene in having a molecular absorption extinction of about $90{\cdot}0 \times 10^3$. The component of molecular weight 596 must, therefore, be a dipyrrylmethene and must be a derivative of III containing two extra hydrogen atoms in one end ring. Such a compound might have a β-methyl-β′-ethyl-hydroxypyrrolidine end ring or, less likely, a terminal open-chain aldehydoamino residue.

The ratio of the two components in stercobilin is not known with certainty but is compatible with their presence in a binary complex. The formation of this, if involving one end ring in a way precluding the extra hydrogenation referred to above, would account for the absence of a component of molecular weight 598. Any such complex must, however, be unstable under the conditions of mass spectrometry since the spectra show no component of molecular weight 1180. A binary composition for stercobilin might have been suspected from earlier unpublished studies in which X-ray analysis proved impossible because of crystal twinning. Similar indications result from studies[10] of the optical activity of the urobilins which arises from asymmetric carbon atoms in the end rings and from the non-coplanarity of the two middle rings[9,10]. Coordination of *d*-urobilin and *d*-urobilin IXα with zinc decreases optical activity, as would be expected from planarization of the molecule; the changes in optical rotation of stercobilin were complex[10], as were the accompanying spectral changes, and suggest that an intermediate complex was formed or that the free pigment was not a single entity.

Consistent with our results for urobilin IXα (ref. 11) is its recent optical 'resolution' by fractional crystallization into dextro- and laevo-rotatory forms[12]. Such a separation would be unlikely if the two components were simple enantiomorphs. The demonstration that the optically inactive urobilin IXα contains a component similar to or identical with *d*-urobilin would suggest that the component of molecular weight 592 might have a laevorotation equal and opposite to that of *d*-urobilin. Similarly the component of stercobilin with molecular weight 596 might be racemic, *d*-rotatory, or have a low *l*-rotation of sufficient magnitude to reduce the molecular rotation from $-31{\cdot}0^\circ \times 10^3$, numerically equal to that of *d*-urobilin, to the $-25{\cdot}0^\circ \times 10^3$ characteristic for stercobilin.

These results will undoubtedly lead to some revision of our ideas of the interrelationships of the three urobilins which may be isolated from faeces under various circumstances. It seems likely that the three components now identified are indeed formed in the gut, but that these might consist of *d*-urobilin molecular weight 588, an *l*-rotatory compound molecular weight 592 and a racemic, *d*-rotatory or weakly *l*-rotatory compound of molecular weight 596. Under some circumstances *d*-urobilin will predominate; it may otherwise become associated with an equimolecular amount of the 592 compound and the isolated material will consist of urobilin IXα. Under other conditions 592 and 596 compounds will be available and the material isolated will consist of the laevorotatory stercobilin. This would undoubtedly account for the unpredictable proportions of urobilin IXα, *d*-urobilin and stercobilin excreted independently of diet or disease[13]. If some of the molecular species are labile and only stable when associated with a second species it may also explain how the yields of these compounds are so poor during isolation from faeces.

We thank Prof. C. Djerassi and his colleagues (Stanford) for help with the initial determination of some of these spectra. This work follows on from a joint study of the mass spectrometric behaviour of mono-[14], di-, tri- and tetra-[15] pyrroles carried out at both Liverpool and Stanford Universities. We thank Prof. G. W. Kenner for his interest in this work.

Note added in proof. Since completion of this work a sample of racemic stercobilin obtained by Watson's method[8] has become available to us, and Prof. Plieninger has kindly provided a sample of a racemic, synthetic tetrahydro-*i*-urobilin. These on mass spectrometry also show the characteristic peaks at *m/e* 592 and 596 described for natural stercobilin and also a less intense peak at *m/e* 594. The possibility cannot, therefore, be entirely excluded that natural stercobilin is indeed wholly of molecular weight 594 as required by structure III and that the molecules of mass 592 and 596 appearing on mass spectro-

metry are artefacts arising as a consequence of a novel disproportionation which may be sterically controlled.

HUMAN GASTRIN: ISOLATION, STRUCTURE AND SYNTHESIS

Isolation of Two Gastrins from Human Antral Mucosa

GREGORY and Tracy[1] have described the isolation from hog antral mucosa of two heptadecapeptide amides which are believed to represent the antral hormone gastrin; they were named gastrins I and II. There followed in this journal a report of the elucidation of their structures[2] and their total synthesis[3] together with an account of the physiological properties of a series of synthetic peptides structurally related to gastrin I[4]. It was shown that all the physiological actions displayed in appropriate experimental conditions by the gastrins (on gastric acid and pepsin secretion, pancreatic volume-flow and enzyme secretion, and gastro-intestinal tone and motility) were possessed by the C-terminal tetrapeptide amide, but that these activities were largely abolished by removal from this structure of the amide group masking the C-terminal residue. These observations were confirmed and extended by a subsequent study of the physiological actions of a series of synthetic analogues of the tetrapeptide[5].

In the ensuing accounts a description is given of the isolation from human antral mucosa of two heptadecapeptide amides (H. I and H. II). Structural and synthetic studies show that these differ from peptides obtained from hog mucosa only in that the methionine residue in position 5 is replaced by leucine; H. II is the tyrosine sulphate ester of H. I.

Antra were collected from Liverpool hospitals immediately after removal from patients undergoing partial gastrectomy. The mucosa was removed in strips, boiled for 5 min in water, and the cooked strips and liquor stored in a dry-ice container until material from approximately twenty antra had been accumulated. After thawing, strips and liquor were homogenized and boiled for 20 min in 5 l. of water. The extract was clarified by centrifugation and filtration and the gastrin recovered from it by adsorption on DEAE floc and elution with 0·1 N sodium hydroxide as previously described for hog gastrin[1]; after neutralization to *p*H 7 with dilute sulphuric acid the extract was freeze-dried. A similar procedure was followed in Los Angeles and the powder sent by air to Liverpool.

The subsequent procedure of isolation was as previously described for hog gastrin[1] except that the isopropanol extraction (from 100 ml.) was performed three times and the final aqueous residue was freeze-dried to a small volume (15 ml.) before precipitation at *p*H 4. The 'Sephadex' column was of smaller size (3 cm × 50 cm) and smaller samples were collected (2·5 ml. every 15 min). The aminoethylcellulose column was smaller (1 cm × 10 cm) and was packed with Whatman powder type *AE* 41; samples of 1·3 ml. were collected every 15 min and a gradient of 0·05–0·5 M ammonium bicarbonate solution was established by feeding the column through a magnetically stirred mixing vessel of volume 180 ml.

Fig. 1 shows a typical run; H. I emerges first, followed by H. II. The appropriate samples were pooled and freeze-dried until free from ammonium bicarbonate. Because

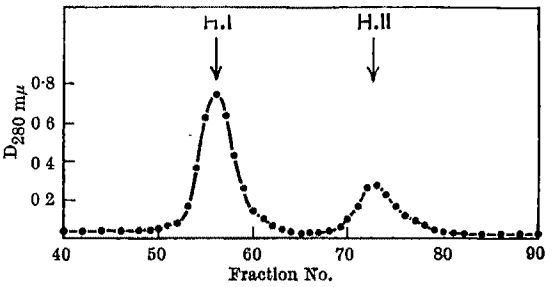

Fig. 1. Isolation of human gastrins (H. I and H. II) from an extract of antral mucosa by gradient elution on aminoethylcellulose in ammonium bicarbonate buffer

of the excellent separation and symmetrical form of the peaks, and the small amounts of material present, no attempts were made to re-run each fraction, or to weigh the products; the yields were calculated later from the data obtained during quantitative amino-acid analysis. Small aliquots were reserved for physiological studies. The highest yields obtained were from a batch of 23 antra all collected in Liverpool; this gave 1·35 mg of H. I and 0·79 mg of H. II. This predominance of H. I over H. II (the sulphated form) contrasts with a ratio of about 3 : 4 found in the hog gastrins[1].

Physiological studies. H. I. and H. II showed in apparently identical form and degree the range of physiological actions already described for the hog gastrins[1]; a further account of these will be presented elsewhere. In view of the previous investigations already mentioned, this was to be expected, since their structures are almost identical with those of the hog gastrins, differing in respect of only one residue which is situated in what has been shown to be the 'non-essential' portion of the molecule[4].

Structures of Human Gastrins I and II

IN the preceding communication, Gregory, Tracy and Grossman[1] described the isolation of two gastrins (H. I and H. II) from human antral mucosa. Small samples of both hormones were generously made available to us by Prof. Gregory, and we now present evidence from degradative investigations supporting the assignment of

structures I and II to the human gastrins H. I and H. II respectively. These structures differ from those of the porcine hormones[2] G. I (III) and G. II (IV) only in the replacement of the methionine residues at position 5 by leucine residues. Synthetic evidence confirming the suggested amino-acid sequence of the human hormone H. I is described in the following section[3].

$$\begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad R \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ \text{pGlu.Gly.Pro.Try.}\textit{Leu}\text{.Glu.Glu.Glu.Glu.Ala.Tyr.Gly.Try.Met.Asp.Phe.NH}_2 \\ 1\quad 2\quad 3\quad 4\quad 5\quad 6\quad 7\quad 8\quad 9\quad 10\quad 11\quad 12\quad 13\quad 14\quad 15\quad 16\quad 17 \end{array}$$

I, R=H; II, R=SO_3H

$$\begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad R \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ \text{pGlu.Gly Pro.Try.}\textit{Met}\text{.Glu.Glu.Glu.Glu.Ala.Tyr.Gly.Try.Met.Asp.Phe.NH}_2 \end{array}$$

III, R=H; IV, R=SO_3H

At the outset of this work only very small quantities of the hormones had been isolated, and the approximate amino-acid compositions were necessarily determined on samples of only 0·02–0·03 μmole (0·04–0·06 mg) using a Beckman amino-acid analyser 120*B* fitted with a high-sensitivity optical system. Typical analyses of acidic hydrolysates of H. I and H. II are recorded in the first two columns of Table 1, and these may be compared with the known composition of porcine gastrin shown in the last column. These results immediately confirmed the close chemical relationship of the human and porcine hormones already suspected from their identical physiological and chromatographic properties[1]. However the human hormones each contained one residue less of methionine and one residue more of leucine than did the porcine hormones. The analytical results for glutamic acid were ambiguous, and initially no decision could be reached between the presence of five or six residues in each gastrin. It has since been realized that the discrepancies between the results in columns 1 and 2 of Table 1 and the strictly stoichiometric theoretical ratios were a consequence, not of the presence of impurities carried through the isolation procedure, but of the presence of traces of contaminants in the ammonium bicarbonate used in the preparation of buffer solutions. No method was found for the preparation of ammonium bicarbonate (even from gaseous ammonia and carbon dioxide) which did not eventually yield traces (*c.* 0·0001 per cent) of individual amino-acids after hydrolysis. Even these minute amounts were significant because the quantities of gastrin isolated were very small (less than 0·1 mg in the early experiments) and the volumes of buffer solution involved in the chromatographic procedures were relatively large. The amino-acid analysis of H. II, approximately corrected for this contamination, is shown in the third column of Table 1, and it strongly supports the presence of six glutamic acid residues, as in the porcine hormones. This result has since been confirmed both by enzymatic degradation (*infra*) and by concurrent investigations of syntheses.

Table 1. Amino-acid Analysis of Human Gastrin

	H. I	H. II	H. II corrected	G. I
Aspartic acid	1·05	1 01	1·01	1
Glutamic acid	5·46	4·92	5·83	6
Proline	1·08	0·79	0 97	1
Glycine	2 02	1·97	2 04	2
Alanine	1 00	1·00	1·11	1
Methionine	0·76	0 76	0 93	2
Leucine	0 95	0·88	1·02	0
Tyrosine	0·92	0·86	0·91	1
Phenylalanine	0 88	0 85	0 94	1
Tryptophan*	~2	~2		2

* By ultra-violet spectroscopy.

That the relationship between the human hormones H. I and H. II was the same as that between G. I and G. II (that is, H. II was the sulphated analogue of H. I) was suggested by their relative electrophoretic mobilities. Confirmation was provided by alkaline hydrolysis of H. II, which yielded tyrosine-*O*-sulphate in place of the tyrosine from H. I.

From the amino-acid compositions of the human gastrins, we adopted as a working hypothesis for investigations of syntheses two possible structures for each hormone. These were the structures which we had previously established for the porcine hormones (that is, III and IV)[2], in which one or other of the two methionine residues had been replaced by leucine. No experimental information was available favouring substitution at position 5 over position 15, although intuitively it was felt that the former was more likely since, in the porcine series, the structure of this part of the molecule has been shown not to be critical for biological activity[4]. While this synthetic work was in progress, however, a larger sample of human gastrin (*c.* 0·6 mg of H. I) became available, and was used in a single degradative experiment designed to locate the leucine residue.

In parallel experiments, approximately equal samples of G. I and H. I were digested by papain at *p*H 7·5 during 26 h at 37° (enzyme : substrate ratio 1 : 9). The resulting mixtures of peptides were separated by paper electrophoresis at *p*H 6·5. Development of end strips by the Ehrlich and ninhydrin reagents revealed fourteen distinct bands in the digest of H. I and thirteen in the digest of G. I. Apart from a single band at the origin in the electrophoresis pattern of H. I (which proved to be derived from a contaminant) the two patterns were quite similar, although differences in the relative intensities of corresponding bands were evident. The most prominent bands were eluted, corresponding eluates in the H. I and G. I series were compared and checked for purity by thin-layer chromatography, and analysed quantitatively for amino-acid content. The presence of tryptophan in peptides was inferred either from the ultra-violet spectrum or from a positive Ehrlich reaction. The following peptides were especially significant.

A strong, ninhydrin-positive band near the origin from the digests of both H. I and G. I corresponded approximately in composition to the expected mixture of neutral peptides derived principally from the C-terminus of the gastrin molecule. The H. I peptides, like those from G. I, contained methionine but no leucine. A strong, ninhydrin-negative, mono-acidic band from the H. I digest was pure by thin-layer chromatography and analysis, and had the composition (Glu,Gly,Pro,Try,Leu). It was clearly derived from the N-terminus (residues 1–5). The corresponding band from the G. I digest, although less pure, contained the expected fragment of composition (Glu,Gly,-Pro,Try,Met). A weak adjacent band in the H. I digest was not obtained pure, but had the approximate composition (Glu,Gly,Pro,Try) and contained a component which corresponded on thin-layer chromatography with a synthetic sample of the N-terminal tetrapeptide pGlu-Gly.Pro.Try. The foregoing results located the leucine residue at position 5, and this was further confirmed by the isolation of a pure, ninhydrin-negative di-acidic peptide of composition (Glu,Gly,Pro,Try,Leu,Glu) (that is, residues 1–6). Two strongly acidic ninhydrin-positive peptides from H. I had the compositions Glu_4,Ala,Tyr, Gly and Glu_5, Ala, Tyr, Gly, which established the presence of five residues of glutamic acid in the central part of the molecule and hence a total of six residues, as in the porcine hormones. No evidence was obtained for any difference between the human and porcine gastrins apart from the leucine-methionine interchange at position 5.

Although the foregoing results do not prove the structure of human gastrin I in detail, they provide very strong support for the suggested single-residue interchange relationship with porcine gastrin. Interchange of methionine and leucine residues has been encountered previously in cytochromes from different species[5]. It is interesting to note that sheep gastrin, which is also under investigation in these laboratories, appears to contain a valine residue at position 5 as well as replacement of other amino-acids. Methionine, leucine, and valine are all related to one

another by single-base exchanges in their respective triplet nucleotide codons[6], and the differences at position 5 in the gastrins of the three species may therefore be a consequence of single mutations during the differentiation of the species.

Synthesis of Human Gastrin I

Analytical work[1] showed that human gastrin I contains one residue each of leucine and methionine, whereas porcine gastrin I contains two residues of methionine (at positions 5 and 15) but no leucine[2]. A plausible hypothesis was that leucine occupies either position 5 or 15, more likely 5 because 15 is part of the 'essential' C-terminal tetrapeptide sequence[3], and the rest of the molecule is identical with that of porcine gastrin I. However, because only minute quantities of the human hormone were available, there was initially ambiguity whether it contained five residues of glutamic acid or six, like porcine gastrin. Investigations of syntheses, concurrent with further degradative studies, were therefore directed towards three targets, namely: (i) the leucine-5; (ii) the leucine-5 des-glutamic-6; (iii) the leucine-15 derivatives of porcine gastrin I. This communication deals with the first two syntheses; the third will be described elsewhere.

For syntheses of the leucine-5 gastrins we required the N-terminal pentapeptide (Fig. 1, line 5). Benzyloxycarbonyl-tryptophan was condensed with leucine methyl ester by means of di*cyclo*hexyl carbodi-imide, yielding the protected (4–5) dipeptide (Fig. 1, line 1). After hydrogenolysis this was elongated by a procedure (Fig. 1, lines 2–5) exactly analogous to one used in synthesis of porcine gastrin[4]. This was merely the most convenient method with the materials available, and other routes are being explored.

Our first synthesis of porcine gastrin I[4] involved coupling the N-terminal pentapeptide with a central (6–13) octapeptide polyester by the azide method and then finally adding the C-terminal (14–17) tetrapeptide amide. Some difficulties were encountered in the first coupling, because reaction between the (1–5) azide and the penta-*t*-butyl monomethyl ester of the (6–13) octapeptide was sterically hindered and side reactions became important. In the meantime, the scheme has been improved by reversal of the order in which the three main components are joined, that is, a (6–17) dodecapeptide amide is constructed and then finally the (1–5) pentapeptide is added. The main advantage of this procedure is that all the protective *t*-butyl groups can be stripped from the dodecapeptide amide before the final azide coupling, which is no longer sterically hindered. Moreover, the (6–17) dodecapeptide amide (Fig. 1, line 6) could also be used directly in convenient syntheses of derivatives of porcine gastrin I differing near the N-terminus, for example the leucine-5 derivative, our target (1).

Preparation of the (6–17) dodecapeptide amide was accomplished by a few modifications of the previous scheme[4]. The (6–13) octapeptide polyester was provided with an N-terminal *t*-butyloxy-carbonyl group by condensation of α-2,4,5-trichlorophenyl γ-*t*-butyl *t*-butyloxycarbonylglutamate with the tetra-*t*-butyl monomethyl ester of the (7–13) heptapeptide (Fig. 1, line 2). Selective saponification of the methyl ester, in the manner already described[4], gave an acid (Fig. 1, line 4), which was coupled, by way of its mixed anhydride, with diphenyl phosphoric acid, with the (14–17) tetrapeptide amide. Treatment with 98 per cent trifluoroacetic acid for 1 h at 20° removed all the protecting groups and the resultant (6–17) dodecapeptide amide was purified by successive chromatography on 'Sephadex *G*25' (in 0·4 per cent ammonium bicarbonate) and aminoethylcellulose (gradient elution with 0·4–2·0 per cent ammonium bicarbonate). The homogeneity of this compound was checked by electrophoresis, thin-layer chromatography, and amino-acid analysis after hydrolysis with leucine-aminopeptidase. The lower homologue, the (7–17) undecapeptide amide, was prepared in the same way from the tri-*t*-butyl monomethyl ester of the (8–13) hexapeptide.

The triethylammonium salt of the (6–17) dodecapeptide amide was coupled in dimethylformamide at 0° C with two equivalents of the (1–5) pentapeptide azide (Fig. 1, line 6), prepared from the methyl ester by treatment with hydrazine and then aqueous diazotization[5]. After 18 h a second equal portion of the azide was added and the mixture

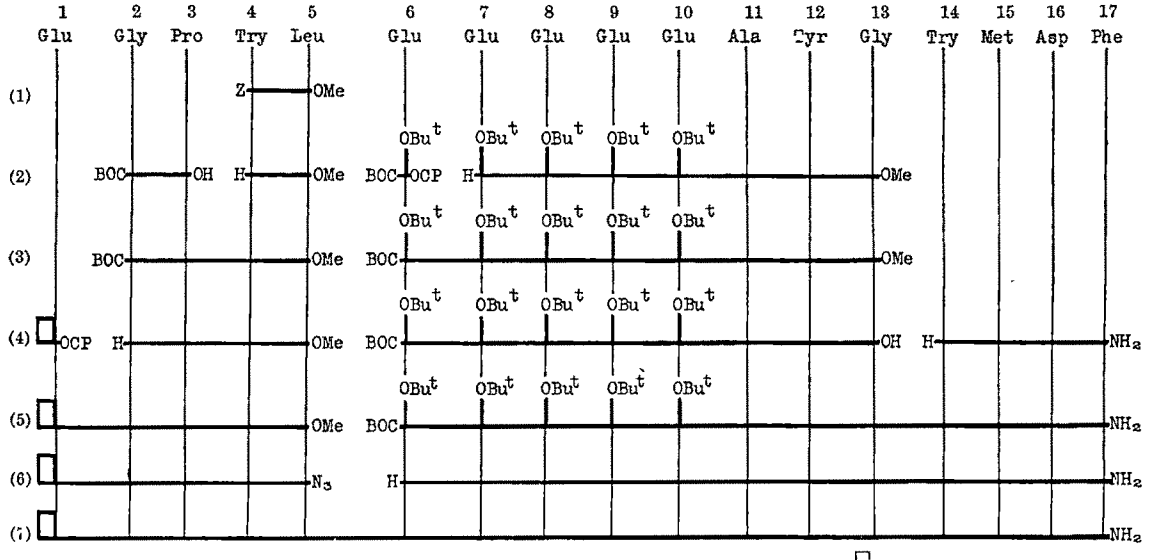

Fig. 1. *Z*, $C_6H_5.CH_2.O.CO$, *BOC*, $(CH_3)_3C\ O.CO$; *Bu*^{t}, $C(CH_3)_3$, *OCP*, $O.C_6H_2Cl_3(2,4,5)$; $^{\square}$Glu, pyroglutamyl

was left at 0° C for 3 days. The product was purified by chromatography on aminoethylcellulose. On rechromatography it was eluted as a single peak like natural human gastrin I, and was indistinguishable by electrophoresis. On the other hand, the lower homologue prepared in the same way from the (7–17) undecapeptide amide had clearly different electrophoretic mobility ($E^{6.5}_{glu}$ 0·65 instead of 0·70). The ambiguity concerning the content of glutamic acid was thus removed.

The heptadecapeptide amide (Fig. 1, line 7) was fully active in stimulating gastric secretion, and its identity with human gastrin I was confirmed by parallel degradations of the natural and synthetic hormones by papain, following the methods used in the structural analysis[1]. The peptides from the six most prominent electrophoretic bands were examined by thin-layer chromatography (three systems in each case); the chromatographic patterns were identical in the location of both major and minor components and their relative proportions. We regard this fingerprinting process as providing definite proof of the structure of human gastrin I. Experiments on the synthesis of human gastrin II are being undertaken.

Throughout this work the L-forms of amino-acids were used, and at each stage the peptides gave satisfactory amino-acid analyses (Beckman 120*B*). We thank Imperial Chemical Industries Pharmaceuticals Division for the gift of the analyser and for other generous support.

ORIGIN OF URINARY METHYLATED PURINES

By DR. LEWIS R. MANDEL, PROF. P. R. SRINIVASAN and PROF. ERNEST BOREK

The School of Pharmacy, Columbia University, and the Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York, N.Y.

ALTHOUGH the occurrence of 7-methylguanine in normal human urine was reported nearly 70 years ago[1,2] and subsequently, a variety of other methylated purines have been found as excretory products[3], their metabolic origin has remained obscure until recently. The meticulous investigations of Dunn *et al.*[4–6] established the presence of methylated purines and pyrimidines in transfer RNA as well as in DNA. The demonstration that all the methyl groups in methylated purines and pyrimidines in RNA (ref. 7) stem from the methyl group of methionine offered a possible new approach to the quantitative investigation of these excretion products. If after the administration of (methyl-^{14}C)-methionine the methylated purines of the urine become specifically labelled, this would offer a greater ease of identification and quantitation.

In this article we report that the methyl groups of the urinary purines stem from methionine. We also present the results of an investigation of the excretion of methylated purines in normal animals compared with animals bearing tumours originating from a thymic lymphoma or from a mouse mammary carcinoma. During the course of these investigations a previously unidentified excretion product—described as compound *S* by Weissmann *et al.*[3]—was tentatively characterized as 1-methyladenine.

Twenty-four male Wistar–Furth rats weighing 180–235 g were divided into two groups. One group served as the control and the other received subcutaneous implants of transplantable thymic lymphoma, strain *W*52. The animals were fed powdered Lablox rat food and water containing 10 per cent glucose and 1 per cent sodium chloride *ad lib.* Fifteen days later, 17 μc. of (methyl-^{14}C)-methionine (0·3 ml.; specific radioactivity 13·4 μc./μmole) were injected intraperitoneally into each of the twenty-four rats. The animals were housed in metabolism cages and the urine samples were collected over chloroform. The urinary output for the first 13·5 h of the normal and the leukaemic rats was pooled separately, and the output for the next 10·5 h was also collected and pooled as before. The preparation of the urinary purine concentrate and the identification of the purines were carried out essentially by the methods outlined by Weissmann *et al.*[3].

The urines were acidified to *p*H 2, diluted with an equal volume of water, refrigerated overnight and then filtered. The filtrate was then passed slowly through a column containing 100–200 ml. of 'Dowex 50 H^+' (20–50 mesh, 8 per cent cross-linked). The column was then washed with 2 l. of water and the purine bases were eluted with 1 l. of M ammonium hydroxide. The ammoniacal elute was concentrated to about 30 ml. and the *p*H adjusted to 2. Then 7 ml. of 1 M silver nitrate was added and the mixture was stored in the dark for a day at room temperature and for two more days at 5° to complete the precipitation of silver purine salts. The precipitate thus obtained was collected by centrifugation and was washed three times with 10 ml. portions of water. The silver purinate was decomposed by stirring in a boiling-water bath for 5 min with 100 ml. of 0·05 N hydrochloric acid. The precipitated silver chloride was removed by filtration and the filter was washed once with 50 ml. of hot 0·05 N hydrochloric acid. The filtrate and the washings were combined, concentrated to about 10 ml. and allowed to stand overnight at 5° to permit separation of additional insoluble material.

Aliquots of the purine concentrate were subjected to column chromatography on 25 ml. columns of 'Dowex 50 H^+' (8 per cent cross-linked; 200–400 mesh) according to the methods of Weissmann *et al.*[3]. The contents of the tubes contained within well-defined peaks were pooled, concentrated and subjected to two-dimensional chromatography in the solvent systems described by Weissmann *et al.*[3], the ultra-violet absorbing spots with corresponding blanks were eluted with 0·05 N hydrochloric acid and their spectra determined. An equal portion of each solution was then transferred to a stainless-steel planchet, dried and counted for determination of radioactivity.

For the investigation on normal mice and on mice bearing mammary carcinoma, 10 μc. of (methyl-^{14}C)-methionine (0·2 ml.; specific radioactivity 23 μc./μmole) were introduced intraperitoneally into each of ten normal *C*-57 mice and into ten mice which carried mammary carcinoma 755. The mice were then placed in metabolism cages and urine was collected for 24 h over toluene. The urines were pooled separately and processed

essentially by the methods described earlier (urine volumes, column volumes, elution volumes, etc., were smaller in this experiment). This time the purine concentrates were chromatographed on paper directly without prior separation on the second 'Dowex 50' column. In these experiments a windowless gas-flow counter with a high counting efficiency was used for determining total radioactivity in urine and purine concentrates and an end-window counter was used to measure total and specific radioactivities of purines.

The results obtained with normal rats and with rats with thymic lymphoma are summarized in Tables 1 and 2. The purine concentrate of the tumour-bearing rats has approximately twice as much radioactivity as that of normal rats. An analysis of the various purines present in this fraction shows that the content of radioactivity in major bases such as adenine and guanine is practically negligible and that most of the activity is located in the methylated purines. Moreover, the specific radioactivity of urinary 7-methylguanine is approximately 2·5 times higher than that of 1-methyladenine and 1-methylhypoxanthine in both the normal and tumour-bearing animals in the first 13·5 h after administration of the (methyl-^{14}C)-methionine. This is probably due to the greater turnover or depurination of 7-methylguanine as compared with other methylated purines. This view is supported by the finding that the specific activity of 7-methylguanine rapidly decreases after the first 13·5 h and falls to one-third of the initial value during the next 10·5 h (Table 2).

The higher levels of radioactivity in the urinary purine fraction of tumour-bearing animals may be a reflexion of a generalized increase in the excretion of the methylated purines studied or of any one of them.

Examination of the results (Tables 3 and 4) obtained with normal mice and mice bearing mammary carcinoma tumour reveals a pattern similar to that from leukaemia tumour-bearing rats. The purine concentrate from the urine of mice with mammary carcinoma had almost twice the radioactivity of normal controls. As before, the major bases contained negligible radioactivity. The specific radioactivity of 7-methylguanine in normal and tumour-bearing mice is at least 2–2·5 times that of 1-methylhypoxanthine and 1-methyladenine. Moreover, the total radioactivity present in the 7-methylguanine from the urine of tumour-bearing animals is approximately 1·8 times that obtained in the case of the normal mice. The total radioactivity in the other two methylated bases, that is, 1-methyladenine and 1-methylhypoxanthine, is similar in both normal and tumour-bearing mice and is considerably lower than that of 7-methylguanine. Thus, the increased radioactivity seen in the purine concentrate of mice with tumours can be attributed to a two-fold increase in the excretion of 7-methylguanine.

Several other ultra-violet absorbing excretion products (designated as compounds *S*, *V*, *W*, and *Z*) were found in human urine specimens by Weissmann *et al.*[3]. We have been able to identify tentatively one of these products—compound *S*—as 1-methyladenine[8] on the basis of the following criteria: (1) The specific radioactivity of compound *S* isolated from rat and mouse urine is comparable with that of 1-methylhypoxanthine (Tables 2 and 4). (2) The absorption spectra of compound *S* and 1-methyladenine are identical (Table 5). (3) The R_F values in three chromatographic solvent systems are similar (Table 5). (4) Preliminary isotope dilution experiments using chemically synthesized 1-methyladenine[9] also suggest that compound *S* is probably identical with 1-methyladenine.

DNA of the mammalian species contains only 5-methylcytosine as the minor methylated base[10]. On the other hand, a variety of methylated purines and pyrimidines are found in transfer RNA. Degradation of transfer RNA would result in the release of all of these minor methylated bases. It is surprising to find 1-methyladenine, 1-methylhypoxanthine, and 7-methylguanine as the predominant methylated bases in the urine of normal and tumour-bearing animals, because these three methylated purines are present in very small amounts in transfer RNA. This apparent paradox may be a reflexion of the absence of enzymes for the degradation of these bases.

Some of the other methylated purines such as 6-hydroxy-2-methylamino purine and 2-dimethylamino-6-hydroxypurine might be metabolized to the corresponding major bases by enzymatic hydrolysis with the concomitant

Table 1. Radioactivity in Urines and Purine Concentrates of Normal and Tumour-bearing Rats

Sample	Urine volume	Total c.p.m. in urine	Total c.p.m. in purine concentrate
Rats with tumours			
1st 13·5 h	310 ml.	$2·0 \times 10^7$	$9·7 \times 10^5$
Next 10·5 h	230 ml.	$3·5 \times 10^6$	$1·5 \times 10^5$
Controls			
1st 13·5 h	530 ml.	$1·5 \times 10^7$	$5·6 \times 10^5$
Next 10·5 h	225 ml.	$1·6 \times 10^6$	$8·1 \times 10^4$

Table 2. Specific Radioactivity of Urinary Purines of Normal and Tumour-bearing Rats

Compound	Controls		Tumour-bearing rats	
	1st 13·5 h (c.p.m./μmole)	Next 10·5 h (c.p.m./μmole)	1st 13·5 h (c.p.m./μmole)	Next 10·5 h (c.p.m./μmole)
Adenine	0	0	0	0
Guanine	1,000	0	0	0
Xanthine	420	250	100	0
Hypoxanthine	180	220	250	180
Compound *V*	500	0	450	0
Compound *S* (1-methyladenine)	6,000	8,000	6,500	4,400
1-methylhypoxanthine	6,200	6,000	5,800	5,300
7-methylguanine *	16,000	5,000	14,000	4,100
8-OH-7-methylguanine †	–	–	–	–
N^2-dimethylguanine ‡	+	+	+	+
1-methylguanine §	+	+	+	+

* 7-methylguanine occasionally gives rise to two spots on the 2-dimensional paper chromatogram. Both spots have similar ultra-violet spectra and specific radioactivity.

† 8-hydroxy-7-methylguanine is not present in rat urine.

‡ N^2-dimethylguanine is present in rat urine. It can be isolated as a highly radioactive purine. However, it is present in trace amounts and it is therefore difficult to obtain an accurate specific radioactivity.

§ 1-methylguanine is present in rat urine. However, it is present in trace amounts and it migrates very closely or together with 7-methylguanine. Consequently it is difficult to isolate it and determine the specific radioactivity.

Table 3. Radioactivity in Urine and in Purine Concentrates of Normal Mice and of Mice with Mammary Carcinoma

Sample	Urine volume	Total c.p.m. in urine	Total c.p.m. in purine concentrate
Control mice	250 ml.	$9·5 \times 10^6$	$1·07 \times 10^5$
Mice with mammary carcinoma	230 ml.	$1·1 \times 10^7$	$1·89 \times 10^5$

n-Butanol : H_2O : HCOOH (77 : 11 : 12)	0·20	0·15
n-Butanol : H_2O : NE_3 (86 : 14 : 5% vapour phase)	0·25	0·22
Isopropanol : H_2O : NH_3 (70 : 30 : 5% vapour phase)	0·53	0·60

production of mono- or di-methylamines. This may be responsible for their extremely low levels in normal urine. It is noteworthy, in this connexion, that the *t*RNA of liver contains only 1-methyladenine in contrast to *Escherichia coli* *t*RNA in which only 6-methyladenine is present[8].

The specific activity of 1-methyladenine is comparable with that of 1-methylhypoxanthine. This could be due to deamination of 1-methyladenine either at the nucleotide or at the polynucleotide level. Since both hypoxanthine and 1-methylhypoxanthine are present in *t*RNA (ref. 11) the interesting possibility of the formation of hypoxanthine and 1-methylhypoxanthine at the polynucleotide level suggests itself (a model for the enzymatic alteration at the polynucleotide-level exists in the methylation of *t*RNA). If such an enzyme for specific deamination of adenine to hypoxanthine should exist, the introduction of degeneracy in the coding properties of *t*RNA might be achieved by it.

The elevated excretion of the methylated purines from the tumour-bearing animals is highly significant in view of the relatively small size of those tumours in comparison to the whole animal. The metabolism which yields the methylated excretory products must be very much higher in the tumour tissue to produce the elevated levels in the total metabolic output.

Elevated excretion of 7-methylguanine and of 8-hydroxy-7-methylguanine has been found by conventional methods of analysis in the urine of human subjects with leukaemia by Weissmann *et al.*[3] and Park *et al.*[12]. It would be interesting to investigate whether the pattern of excretion of methylated purines is similar in other malignancies.

We thank Dr. Jacob Furth, Dr. Akira Kunii and Dr. Eric Hirschberg for supplying tumorogenic material and for instruction in their implantation, and Miss Corry Bettenhausen for assistance in some of these experiments.

The work was supported by grants from the National Institutes of Health, U.S. Public Health Service, and from the National Science Foundation.

CHORIOALLANTOIC MEMBRANE LESIONS PRODUCED BY INOCULATION OF ADULT FOWL SMALL LYMPHOCYTES

By Dr. M. J. SIMONS and Dr. R. FOWLER

Surgical Research Department, Royal Children's Hospital Research Foundation, Parkville, N.2, Victoria, Australia

THE lesions which develop on the chorioallantoic membrane (CAM) following the inoculation of adult fowl leucocytes represent the reaction of immunologically competent cells to histocompatibility antigens present in the membrane[1]. Using whole leucocyte preparations, Szenberg and Warner found that only with the large lymphocyte was there a significant correlation with the number of lesions formed[2]. They concluded that it was this morphological type which was responsible for the production of lesions on the CAM.

Although it was widely held for many years that the small lymphocyte was an end cell, incapable of further reactivity[3], in recent years evidence has arisen for the potential reactivity of some of these cells, and particularly for their important role in immune reactions[4]. Therefore it was decided to re-investigate the CAM phenomenon with the view of establishing whether or not the small lymphocyte could produce the lesions.

In order to obtain pure samples of small lymphocytes, the following procedure was adopted. Adult fowl blood was obtained by cardiac puncture, heparinized and centrifuged at 500 r.p.m. for 4 min to sediment the red cells. 1·0 ml. of the uppermost layer of the supernatant was passed through a column of glass wool and glass beads, following the method developed by Rabinowitz[5]. The first ten drops of the effluent were collected and a white-cell count was performed using a haemocytometer chamber. To ensure that the only cells present in the effluent were small lymphocytes, drops of the cell suspension were placed on glass slides, drawn along the slide by a fine capillary rod, air dried and stained with Leishman stain for 10 min. Cells with dark-staining nuclei and minimal cytoplasm were identified as small lymphocytes. Only aliquots containing 100 per cent pure cell suspensions were used. Such aliquots were inoculated on to the dropped membranes of 12-day-old embryos. The inoculated eggs were incubated at 38° C and the membranes collected at 4–5 days.

Initial experiments demonstrated that these small lymphocyte inocula could produce the characteristic nodular lesions, as shown in Fig. 1.

In subsequent experiments dilutions of cell suspensions were prepared to contain as few as 500 cells/0·1 ml. A summary of the results from seven experiments is given in Table 1.

A typical distribution, as observed in experiment (7), is shown in Fig. 2.

Inocula containing larger numbers of cells often resulted in the appearance of clumped, multi-nodular lesions and this precluded accurate counting. The smaller inocula also produced clumped reactions despite efforts to prevent

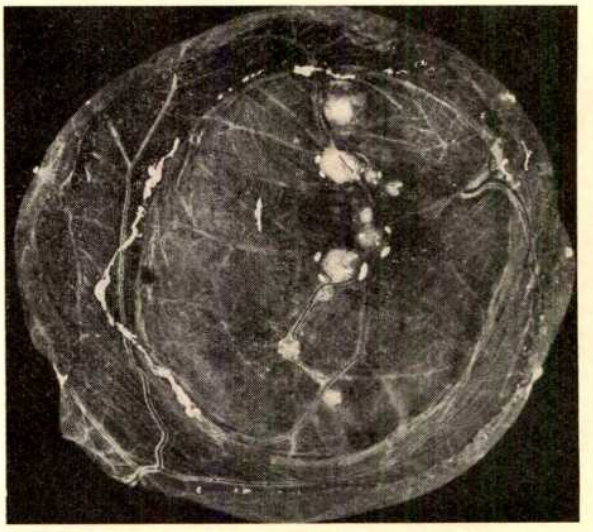

Fig. 1

Table 1

Experiment	Fowl No.	No. of eggs	Mean cell-focus ratio	Lowest cell-focus ratio
(1)	462	35	4,400/1	800/1
(2)	462	32	3,260/1	1,000/1
(3)	462	34	4,600/1	600/1
(4)	468	33	1,140/1	90/1
(5)	468	30	950/1	30/1
(6)	465	31	4,200/1	800/1
(7)	465	55	2,860/1	250/1

their appearance by rolling the eggs at the time of inoculation and frequent turning of the eggs during incubation.

Even with these smaller numbers of cells considerable variation occurred within each experiment in the number of foci produced by the same dilutions, and between each experiment in the mean and lowest cell-focus ratios. There are at least four possible sources of these variations.

The first concerns the genetic relation between the donor fowl and the recipient embryo. A correlation between CAM tests and the homograft response in inbred fowls has been established[6], and evidence presented for the proposal that three major antigens are responsible for histo-incompatibility[7]. From this it follows that the number of fowl cells potentially capable of initiating CAM lesions will vary directly with the degree of genetic disparity between donor and recipient. Also, since only a small number of antigens are responsible for the CAM reaction the variation in cell-focus ratios resulting from the use of genetically different fowls will be correspondingly great. Our results are consistent with these predictions in that, using three non-inbred fowls as donors, it was found that the ratios obtained using the second fowl differed greatly from those from the other two (see Table 1).

The second possible source of variation lies in the sampling of the potentially reactive fowl small lymphocytes. Unless there is a non-random distribution of these cells throughout the peripheral blood of the fowl, then sampling is probably not a major source of variation.

The third possibility arises from the technique of leucocyte separation. If this method involves more than mere physical filtration and some characteristic of the potentially reactive small lymphocytes results in their preferential passage through the column, then some variation might be expected in the number of foci which appear in response to a given number of cells. Possible cell characteristics which have been investigated in this system by Rabinowitz are motility, phagocytic activity and adherence[5]. Furthermore, if these cells have been exposed to some selective pressure resulting in the development of a sub-population of morphologically indistinguishable small lymphocytes which are highly competent for CAM reactivity, then the effect of their preferential passage through the column may result in an even more pronounced cell-focus variation. Alternatively, the facilitated filtration of some small lymphocyte sub-group, independent of its immunological competence, may result in more suitable conditions for CAM reactivity.

The final possibility comprises a group of factors which are peculiar to this biological system. Those related to the embryonic membrane are the varying presence and prominence of the histocompatibility antigens, and the local conditions necessary for potentially competent cells to initiate a reaction. In addition, it is known that all cells do not stay on the membrane, a variable number migrating to form typical nodules in the spleen and less frequently in other sites[8]. The cells that remain may have to be in a particular phase of their generative cycle before their capacity to initiate nodule formation is realized.

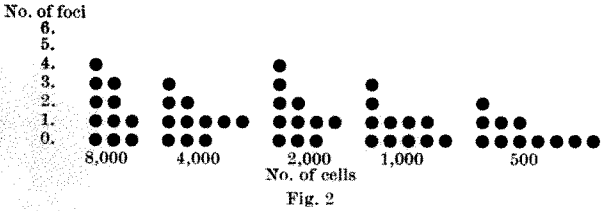

Fig. 2

The effect of any of the factors in this group would result in an under-estimation of the number of competent cells in any given inocula—that is, in a spuriously high cell-focus ratio.

In view of the numerous sources of variation and their likely effect, it is reasonable to attach greater importance to the lower cell-focus ratio for any immunological interpretation. This ratio was as low as 30 : 1 in one experiment (Table 1), a value which approximates to the lower limit of 40 : 1 quoted by Szenberg and Warner[2], for the large lymphocyte. In this connexion it is conceivable that cell suspensions comprised only of large lymphocytes, which have a higher metabolic rate than small lymphocytes and are probably their progenitors, would also be able to produce CAM lesions.

The CAM phenomenon has been proposed as an experimental model which is suitable for testing the clonal selection theory of immunity[9,10]. If each focus does represent the response of a single lymphocyte, and this claim has not yet been established with certainty, then the present results appear to be at variance with the ratios predicted on the basis of this theory. Clonal selection theory postulates a random distribution of patterns of specific reactivity among lymphoid cells permitting each to react only to the corresponding antigenic determinants. The immunological patterns are thought to arise by somatic mutation, and the magnitude of the ratio of cells carrying a genetically predetermined pattern to the total number of cells in a given population has been suggested to be, in the absence of selective pressures, of the order of one in 10,000 (ref. 10). For the observed low order of reactivity to be due to selection of donor fowl cell clones for reaction against allogeneic antigens present in the embryonic membrane, it would be necessary to postulate that such clones had been exposed to identical antigenic determinants during the course of the normal immunological development of the fowl. Although there is no direct experimental evidence on this point, the known specificity of antigens renders this requirement highly improbable.

However, even if some mechanism does exist which favours the development within the apparently uniform population of a sub-group of small lymphocytes, and if all the sources of variation operate so as to favour a low cell-focus ratio, then it is still only just conceivable that one reactive cell might occur every 30 or so cells. So numerous are the sources of variation and so great would be their resultant effect that it does not seem possible to establish whether the CAM phenomenon can be accounted for by an unmodified clonal selection theory.

A modification, which to us seems more consistent with the results obtained in the present experiments, is that a small lymphocyte or other lymphoid cell can be induced to proliferate in response to one or any of several closely related antigenic configurations—the extent of its responsiveness being genotypically determined, and the realization of its responsiveness being influenced by factors associated with the lymphocyte and the membrane cell and their interaction. It is doubtful whether investigations of the CAM phenomenon alone will enable this proposal to be unequivocally established.

We thank Miss M. Fitzgerald for technical assistance.

MECHANISM OF A HISTOCHEMICAL REACTION DIFFERENTIATING BETWEEN ADRENALINE- AND NORADRENALINE-STORING CELLS IN THE ELECTRON MICROSCOPE

By Prof. R. E. COUPLAND and Dr. D. HOPWOOD
Department of Anatomy, Queen's College, Dundee, University of St. Andrews

SOME months ago we published details of a method of fixation and staining recently developed in this laboratory[1], which makes possible the differentiation between adrenaline- and noradrenaline-storing cells in the light and electron microscope. Using this method, the separate identities of the adrenaline- and noradrenaline-storing chromaffin cells, which had been suggested on the grounds of the iodate-staining reaction[2], were established in the adrenals of the adult frog, mouse, rat, cat and domestic fowl. In the rabbit, the majority of adrenal chromaffin cells are adrenaline-storing, while in the extra-adrenal para-aortic chromaffin bodies they are noradrenaline-storing.

More recently work has now established the mechanism of the reaction. Aqueous solutions of noradrenaline react with glutaraldehyde with the production of a dense precipitate. The kinetics and product of the reaction have been examined by ultra-violet and visible light and by infra-red spectroscopy and paper chromatography using various solvent systems; melting-point determinations have been carried out and recrystallization attempted. All findings are in favour of the product being a polymer of glutaraldehyde and noradrenaline combined in a molecular ratio of 1 : 1.

If glutaraldehyde-fixed frozen sections of rat, cat, mouse and fowl adrenal glands are immersed in aqueous osmium tetroxide (1–2 per cent), 3 per cent potassium dichromate, or saturated potassium iodate, the same islands of cells give a colour reaction which is respectively black, yellow or brown. Furthermore, when the chromatograms of the reaction products of the noradrenaline–glutaraldehyde are sprayed, or when the precipitate is dried on filter paper with these oxidizing agents, similar colours are observed. We have been unable to demonstrate a similar reaction between adrenaline and glutaraldehyde by the foregoing methods.

No reactive islands are observed when frozen sections of glutaraldehyde-fixed adrenals of reserpinized Sprague–Dawley rats (5 mg/kg intravenously 24 h previously) are immersed in aqueous osmium tetroxide, dichromate or iodate solution. A reaction confined to specific islands is, however, observed in glutaraldehyde-fixed adrenals obtained from animals starved overnight and killed 2–4 h after an injection of insulin (10 I.U./100 g, subcutaneously). Under these conditions, the reserpine depletes both adrenaline- and noradrenaline-storing cells, while a depletion of the adrenaline-strong cells alone can be observed under the light microscope after treatment with insulin. These findings, together with the chemical evidence, establish the identity of the reactive material as a glutaraldehyde–noradrenaline complex.

In order to assess the importance of glutaraldehyde in this reaction as it relates to electron microscopy, adrenal glands have been fixed in (*a*) Caulfield's buffered (*p*H 7·4) osmium tetroxide-sucrose mixture, (*b*) 4 per cent glutaraldehyde, buffered to *p*H 7·4 with 0·1 M cacodylate, (*c*) 4 per cent buffered glutaraldehyde followed by post-fixation in either 1 per cent buffered (*p*H 7·4) osmium tetroxide or 3 per cent potassium dichromate. Tissue blocks were afterwards dehydrated in ethanol, cleared in 1 : 2 epoxypropane and embedded in 'Araldite'. In view of the recent communication from Benedeczky, Puppi, Tigyi and Lissák[3], only the findings relating to the domestic fowl adrenal will be considered, though similar results have been obtained with rat adrenal glands.

Buffered osmium-tetroxide fixation. In well-fixed and adequately processed normal fowl adrenal glands all chromaffin cells contain large numbers of electron-dense chromaffin granules which exhibit a peripheral limiting membrane (Fig. 1). Many have a target form with an intensely electron-dense centre and a periphery of a more diffuse granular nature.

Glutaraldehyde fixation only. Two distinct types of chromaffin cells may be identified (Fig. 2) in unstained sections and after staining with potassium permanganate or after brief staining with Reynold's lead citrate (20 min). Electron-dense granules, usually of homogeneous nature, represent the noradrenaline-storing elements, while the adrenaline-storing cells contain granules which have a washed-out appearance and show internal granularity. Peripheral limiting membranes of the granules are not visible.

Glutaraldehyde fixation followed by post-fixation in osmium tetroxide or potassium dichromate. Two distinct types of granule are again visible in unstained sections and in sections stained with permanganate or briefly with lead citrate (Fig. 3). One type is intensely electron-dense and homogeneous, the other has a washed-out appearance and shows internal granularity. The former is found in the cells giving a positive colour reaction for the noradrenaline–glutaraldehyde complex, the latter in others presumed to store adrenaline. In tissues post-fixed in osmium tetroxide, both types of granules show a peripheral limiting membrane, while in those post-fixed in potassium dichromate typical peripheral membranes are not seen.

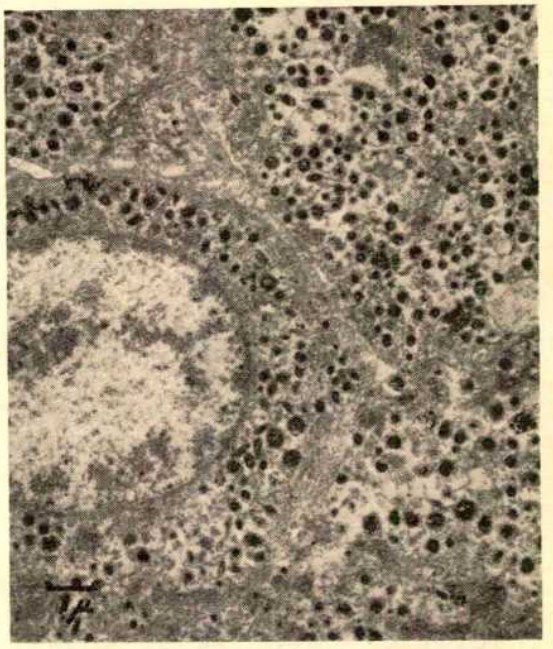

Fig. 1. Chromaffin cells of domestic fowl adrenal fixed only in buffered osmium tetroxide. All cells contain strongly electron-dense chromaffin granules

Since the previously mentioned findings indicate that glutaraldehyde is the essential reactive chemical in this method of differentiating adrenaline- and noradrenaline-storing cells, it was of interest to determine the fate of adrenaline, which is apparently unaffected by glutaraldehyde.

Various tests on mixtures of adrenaline and glutaraldehyde revealed that, for about 1 h after mixing, the secondary amine was still oxidizable with iodine and indeed that the method of Euler and Hamberg[4] could be applied to determine the quantity present. Glutaraldehyde had no effect on this colorimetric method. This method was, therefore, used to determine whether the adrenaline remained *in situ* or diffused out of the tissues during the course of fixation. Pieces of adrenal gland about 1–2 mm³ in volume were fixed 4 h in ice-cold cacodylate-buffered 4 per cent glutaraldehyde. During the fixation period the stoppered specimen jar was occasionally inverted to ensure adequate contact of fixative and tissue. Tissues were then dehydrated in the normal way in ethanol. Fixative and alcohols were assayed for adrenaline and noradrenaline and the results compared with those obtained by assaying homogenates (in 0·01 N hydrochloric or 0·4 per cent perchloric acid) of pieces of the same gland. Catecholamines present in homogenates were adsorbed on an alumina column[5], and eluted with 0·2 M acetic acid prior to colorimetric assay. The results, corrected for column yield (80 per cent), are shown in Table 1, and indicate that the majority of the adrenaline is lost during glutaraldehyde fixation and dehydration. This fact, together with the production of the glutaraldehyde–noradrenaline polymer, accounts for the differential staining reaction.

Table 1. CATECHOLAMINE CONTENT OF 4–6-MONTH-OLD COCK ADRENALS

Homogenate CA μg/g adrenal		Fixative + alcohols CA μg/g adrenal		Loss A
A	N	A	N	
4,310	3,180	4,100	0	95
4,800	2,300	4,700	0	98

CA = catecholamines, A = adrenaline, N = noradrenaline.

It is worth noting that the staining reaction of the glutaraldehyde-fixed noradrenaline-storing cells can be obtained many months after tissue fixation, provided the cells are stored in water, saline or glutaraldehyde. Hence,

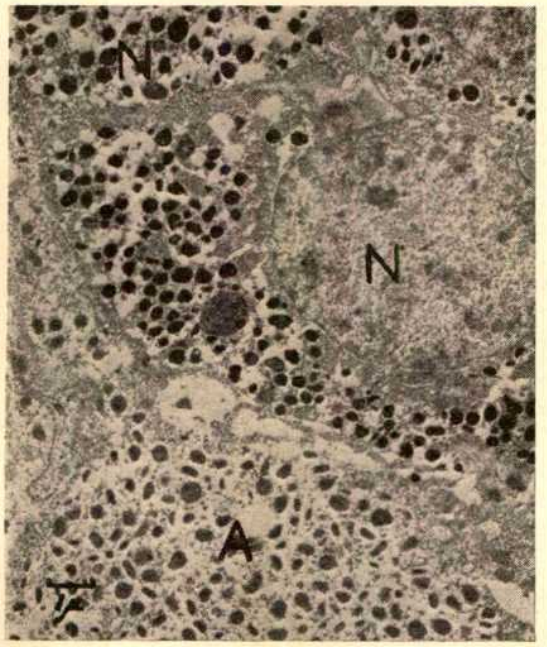

Fig. 2. Chromaffin cells of domestic fowl adrenal fixed only in buffered glutaraldehyde. Chromaffin granules of noradrenaline-storing (*N*) cells are strongly electron dense, while those of adrenaline-storing (*A*) cells show only moderate electron density

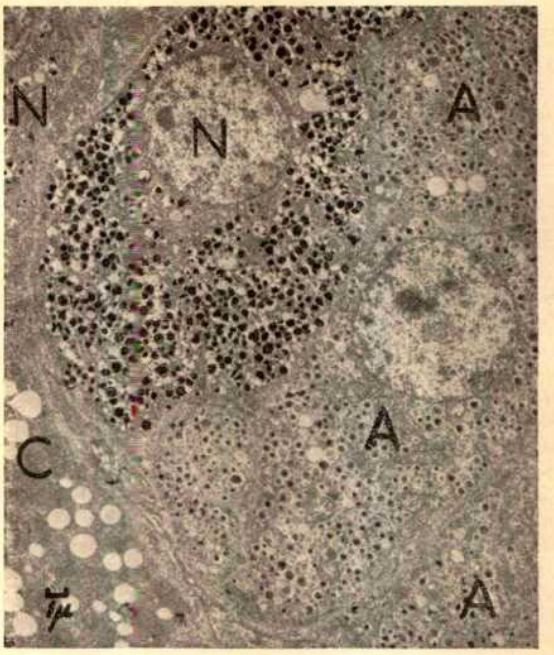

Fig. 3. Domestic fowl adrenal gland fixed initially in buffered glutaraldehyde and afterwards in osmium tetroxide showing noradrenaline-storing (*N*) cells with very strongly electron-dense granules, adrenaline-storing (*A*) cells with moderate electron-dense granules and cortical (*C*) cells

a delayed chromium, osmium or iodate reaction may be performed on frozen sections of this material. If the tissues are embedded in paraffin prior to treating with oxidizing agent, the reaction is reduced considerably and is of little histological value so far as the light microscope is concerned; block impregnation of glutaraldehyde-fixed adrenal with osmium tetroxide or potassium dichromate prior to embedding in paraffin does, however, result in a good demonstration of the noradrenaline islands, and this technique, or the use of frozen sections, is the method of choice for light microscopy.

The glutaraldehyde method for distinguishing between noradrenaline- and adrenaline-storing cells has recently been criticized by Benedeczky *et al.*[3], who claim, quite rightly, that adrenaline is more readily oxidized than noradrenaline; this fact has been generally accepted since 1949, when Euler and Hamberg introduced their colorimetric method for assay of the two amines. Unfortunately Benedeczky *et al.*[3] took no account of the fact that all tissues used by us had been fixed initially in glutaraldehyde, which for reasons given here is the most essential part of the technique. Cells showing morphological characteristics of "the light cell" illustrated by Benedeczky *et al.* may be observed frequently in adrenals fixed only in buffered osmium tetroxide, including glands obtained from animals such as the guinea-pig or rabbit which contain little or no noradrenaline. They are, however, artefacts due to bad fixation and have a specific zonal distribution in the tissue block. Although with care and experience the fixation artefacts associated with buffered osmium-tetroxide fixation of chromaffin tissue can be considerably reduced, more uniformly well-preserved chromaffin cells are obtained by initial fixation in glutaraldehyde followed by osmium tetroxide, which also has the advantage of allowing one to differentiate between the adrenaline- and noradrenaline-storing elements. Adrenaline- and noradrenaline-storing elements cannot be differentiated with certainty in tissues of the rat, mouse, cat, cock or frog fixed only in osmium tetroxide.

VARIOUS CELL TYPES IN THE ADRENAL MEDULLA

By I. BENEDECZKY*, A. PUPPI, A. TIGYI and Prof. K. LISSÁK

Institute of Physiology, Medical University, Pécs, Hungary, and Postgraduate Medical School, Department of Pathology, Budapest, Hungary

MOST electron-microscope and histochemical investigations of the nature of the adrenal medulla have been concerned with the reliable identification of adrenaline-producing and noradrenaline-producing cells. In 1950, and later in 1954, Euler[1] stated that "these two hormones (adrenaline and noradrenaline) are produced in different conditions and it could hardly be imagined that both were synthesized in one and the same cell". This theory was experimentally proved for the first time by Bänder[2] and Eränkö[3], who succeeded in demonstrating the existence of the assumed types of cells by histochemical methods. But with light-microscopy and histochemical methods it was not possible to obtain a satisfactory answer to the question of a possibly different sub-microscopic representation of adrenaline- and noradrenaline-containing granules in these two types of cells. The problem was attacked in a number of different ways by several workers. Hagen and Barrnett[4] isolated, by means of differential centrifugation, a fraction containing 'large granule'-noradrenaline, and one containing 'small granule'-adrenaline from a homogenized granule suspension of the adrenal medulla. Yates *et al.*[5] soon afterwards showed, by electron-microscopic and phase-contrast-microscopic methods, that granules of two orders of magnitude exist in different cells in the adrenal medulla of the golden hamster. Similar observations were made in the grass snake[6]. These workers also demonstrated, by means of differential centrifugation and electron-microscopic examination, the existence of large (2000–3500 Å) noradrenaline-containing secretory granules, and smaller (500–1500 Å) adrenaline-containing secretory granules in the homogenized adrenal medulla of the dog. However, the two types of cells described in the snake could not be identified in ultra-thin sections taken from dog and rat. An entirely different approach to the problem was used by Wassermann and Tramezzani[7]. Using various methods, they found only noradrenaline in the anatomically separable ribbon of the adrenal gland of the snake. With the electron microscope, they found and described noradrenaline granules of the polymorphic type in the medullary cells of the snake. In the central part of the adrenal medulla they found typical circular, membrane-limited adrenaline granules. They also mention that a reliable electron-microscopic demonstration of secretory granules is possible only after prefixation with glutaraldehyde, and that the size of noradrenaline granules is larger than that of the adrenaline granules.

The application of glutaraldehyde prefixation resulted in new possibilities, not only in electron microscope preparation techniques, but also in the electron-histochemical exploration of the adrenal medulla. The possibility of identifying the adrenaline and noradrenaline granules using the electron microscope was described by Coupland[8] and Wood[9] about the same time. According to Coupland[8], the noradrenaline-containing granules have a high internal density in the osmiophylic noradrenaline-storing cells, while the less electron-dense adrenaline granules are typical in the less osmiophylic, adrenaline-storing cells. Wood *et al.*[9], on the other hand, emphasize that, when prefixed with glutaraldehyde, the noradrenaline granules in the adrenal medulla of the golden hamster are highly electron-absorbent after oxidation with dichromate at *p*H 4·1, while if dichromate oxidation occurs at *p*H 6·5, both types of granule become highly electron-absorbent.

Coupland's findings were commented on by Benedeczky *et al.*[10], and they state that the "osmiophylic, noradrenaline-storing cells" ("dark cells" in Benedeczky's nomenclature) can also be identified using formalin prefixation in several animals (frog, grass snake, dog, rat). Benedeczky *et al.* see a relationship between the high internal density of the cells and the secretory granules in the cells, and the 'physiological and ontogenetic' state of the cell. In their recent investigations, Coupland *et al.*[11] have made a detailed analysis of the mechanism and circumstance of the noradrenaline–glutaraldehyde reaction. They suggest a number of proofs showing that this chemical reaction is specific for noradrenaline, and is thus suitable for a sub-microscopic identification of noradrenaline-containing granules, because the substances of adrenaline-containing granules react much less intensely to glutaraldehyde. In Coupland's opinion, the less electron-dense nature of adrenaline granules is due to the fact that the adrenaline content of the granule is dissolved in the course of fixation with glutaraldehyde and subsequent alcoholic dehydration. This circumstance makes it possible to preserve the glutaraldehyde–noradrenaline complex on the electron-microscopic level. Recent photographs[11] have also been taken of the adrenal medulla of the domestic fowl, but it is reported that in the adrenal medulla of the rat, treated with reserpine, it was not possible to identify reactive isolated spots. Thus, the question arises as to whether or not the electron-histochemical method used by Coupland *et al.*[11] is suitable for reliable identification of adrenaline and noradrenaline-containing granules not only in a given species but in the chromaffin cells of any animal, and whether the attempts of other research workers to explain the sub-microscopic appearance of the two types of hormone-producing cells with other methods and interpretations are tenable.

Naturally, it would only be possible to answer this question satisfactorily with a large amount of experimental data. Coupland's method and results seem very convincing, but some circumstances deserve consideration. It is primarily the evaluation of the results obtained with the ultracentrifuge that presents a problem in connexion with Coupland's recent findings. A large number of experiments seem to support the conclusion that the 'large granules', that is, those having a larger diameter and a higher sedimentation rate, contain noradrenaline. After differential-centrifugation of the homogenized adrenal medulla of the domestic fowl we found that 76 per cent of the fraction of large granules (showing a sedimentation rate of 3,000*g*/30 min after the nucleus fraction had been removed) contained noradrenaline. On the other hand, 48 per cent of pellets which settled at a rate of 24,000*g*/min proved to be adrenaline. Entirely similar results were obtained when the homogenized adrenal medulla of the dog was tested[12]. No conclusions on granule dimensions can be drawn from Coupland's illustrations because, owing to the dissolution of adrenaline, the contours of the granules are dimmed. Thus it cannot be decided whether the 'dense noradrenaline' granules show any difference in dimension compared with the adrenaline granules. The problem of how to reconcile the foregoing facts with Coupland's recent results remains, therefore,

* Present address: Postgraduate Medical School, Department of Pathology, Budapest, Hungary.

unsettled, since he has made available no data on the size of adrenaline and noradrenaline granules.

Coupland's results would, in our opinion, be more convincing if he gave data to show whether he has found any parallel between the number of noradrenaline-containing cells and the noradrenaline content measured in the adrenal medulla of the domestic fowl. It is well known that the adrenal medulla of the hen has a relatively high noradrenaline content. According to references in the literature, and our own observations[13], the noradrenaline/adrenaline ratio is about 2 : 1 (5,170 μg/g noradrenaline and 2,609 μg/g adrenaline). Accordingly, we found that the number of cells with small granules (those which, in our opinion, contain adrenaline) was rather low in the adrenal medulla of the domestic fowl after prefixation with formalin. But when prefixation with glutaraldehyde was applied we were unable to find any predominance of 'dense granule' cells (which, in Coupland's opinion, contain noradrenaline). Although Coupland *et al.*[11] give no numerical data on the ratio of adrenaline and noradrenaline cells, in Fig. 3 of their paper it is clear that there are six adrenaline-containing cells for every three noradrenaline-containing cells. But on the basis of our biochemical investigations a ratio of 1 : 1 might have been expected. Despite contradictory data and conclusions, it would seem that there is a possibility of reconciling the views of the two 'schools', if the following observations are taken as a basis. In one of our recent publications[6] we described the finding of cells containing 'small' and 'large' granules in the adrenal medulla of the grass snake after prefixation with formalin. The light transmission of the granules of adjacent cells (on the same photographic plate) was then measured, using a microphotometric apparatus. The results are given in Fig. 1. It can be seen from Fig. 1 that the light transmission of the small granules (500–1500 Å diameter), which, in our opinion, contain adrenaline, is much lower than that of the noradrenaline-containing large granules (2000–3500 Å diameter). Accordingly, the small adrenaline granules in Fig. 2 appear in a much less dense form than the noradrenaline granules of larger diameter, which are highly electron-absorbent. This fact is also clearly shown in the photographs by Wassermann and Tramezzani[7], who applied glutaraldehyde-prefixation. It would seem, therefore, that the noradrenaline granules, whether they are prefixed with formalin or glutaraldehyde,

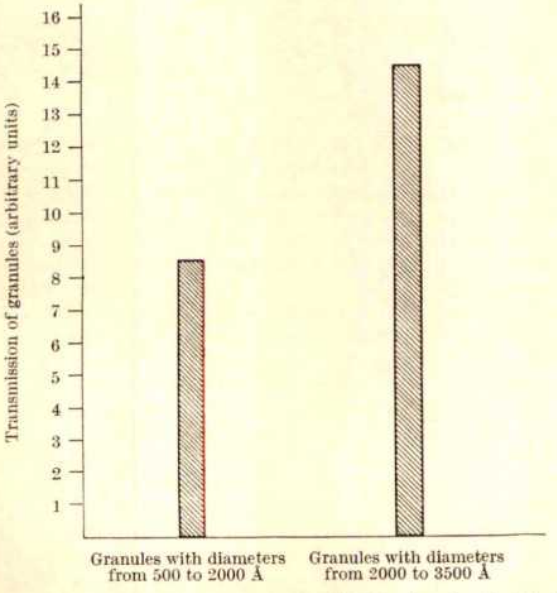

Fig. 1. Light transmission of the 'small' (left column) and of the 'large' (right column) catecholamine granules in the adrenal medulla of the grass snake. It can be seen that the light transmission of the small granules (those which, in our opinion, contain adrenaline) is much lower than that of the noradrenaline-containing large granules

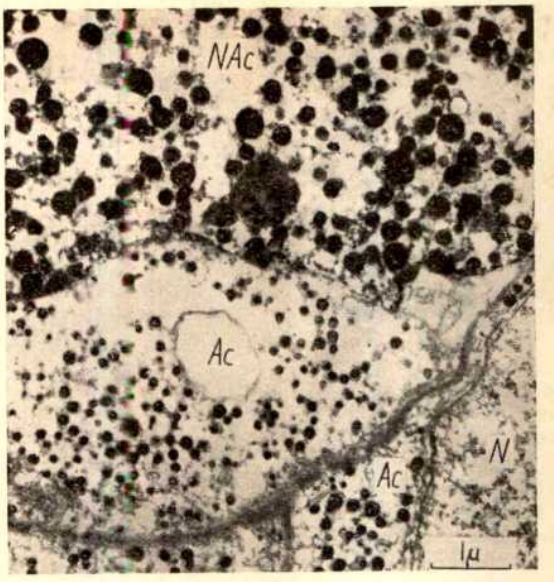

Fig. 2. Chromaffin cells of the grass snake adrenal, fixed in buffered formalin and afterwards in osmium tetroxide. The secretory granules of the noradrenaline cells (*NAc*) are larger and more electron-dense than in the adrenaline cells (*Ac*) (× 10,000)

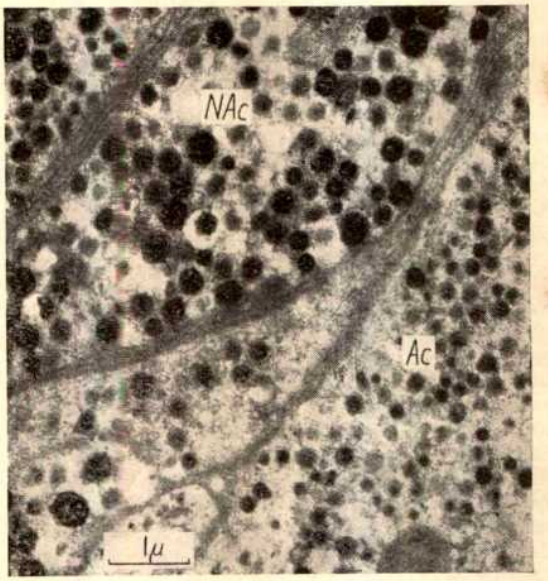

Fig. 3. Grass snake adrenal gland fixed initially in buffered glutaraldehyde and afterwards in osmium tetroxide showing noradrenaline cells (*NAc*) with 'large' (2000–3500 Å diameter) and very strongly electron-dense granules, and adrenaline (*Ac*) cells with moderately electron-dense and 'small' granules (500–1500 Å diameter) (× 10,000)

can be distinguished from adrenaline granules by their larger dimensions and higher internal density. But this electron-histochemical characteristic is not conclusively present in every species. It was not possible, for example, to identify the previously mentioned types of granules in the adrenal medulla of the rat with either formalin or glutaraldehyde prefixation. But both methods of prefixation of the adrenal medulla of the grass snake resulted in the appearance of typical 'small-granule' and less electron-dense cells, and, on the other hand, 'large-granule', highly electron-dense, noradrenaline-containing cells (Fig. 3).

Thus at present there exist some contradictions concerning the types of cells in the adrenal medulla, as different workers have used different techniques and investigated different animals, which makes the evaluation of results difficult. It is to be hoped that in the near

future workers will rely on identical experimental animals, and that it will be possible to resolve the persisting differences of opinion and obtain a more thorough knowledge of the types of cells in the adrenal medulla.

A POSSIBLE FUNCTION FOR THE AXIAL ORGAN OF ECHINOIDS

By Prof. N. MILLOTT

Department of Invertebrate Zoology, Marine Biological Laboratory, Woods Hole, Massachusetts; and Department of Zoology, Bedford College, University of London

As any student of echinoderms is aware, the axial organ is a most puzzling structure. No function has yet been clearly shown for it. Though ideas have not been lacking, there has been much pre-occupation with oversimplified analogies with organs of very different character[1]. This situation arises partly because the living organ has been insufficiently observed and little experimental analysis has been attempted. Inferences as to its function have often been made from studies of its structure. This is especially dangerous where structure is imperfectly understood and it must be admitted that the histology of the organ is exceptionally difficult to interpret.

Recent investigations on echinoids have emphasized three cardinal features of the organ. First, it is permeated by an elaborate contractile structure[2]. Secondly, it is a central point of confluence of perivisceral coelom, 'haemal' system and water vascular system[1]. Thirdly, some echinoids can survive its removal, at least for several months[1].

The present investigation of the axial organs of *Arbacia punctulata* and *Strongylocentrotus dröbachiensis*, in addition to indicating a likely function, has clarified some important anatomical features. Thus, the numerous cavities at the periphery, which give the organ its spongy character, are not entirely 'haemal' as previously supposed, but are of two kinds. One type communicates directly with the perivisceral coelom by the canals already described[1,3]. These spaces constitute a system that is distinct from the 'haemal' spaces which surround them. The 'haemal' spaces can be distinguished by their dense content of cells, together with pigment and debris, some of which appears to be derived from disintegrating amoebocytes. The other spaces are lined by a characteristic shallow epithelium and, with the notable exceptions to be described, often appear relatively empty. The distinction is not absolute, for the walls which separate the two kinds of cavity disappear in places so that the contents of the 'haemal' spaces may enter the complementary spaces (Fig. 2). In the case of *Arbacia*, the peripheral 'haemal' spaces were traced into continuity with the central contractile vessel, through irregular, ill-defined channels permeating the strands of cells that traverse the central lumen of the organ to reach the vessel (Fig. 6). It is therefore evident that fluid from the contractile vessel might come into intimate relation with fluid from the perivisceral coelom at the periphery of the axial organ, since the two kinds of cavity are separated, at most, by the attenuated epithelium just mentioned.

Although the importance of the existence of canals by which the axial organ communicates with the perivisceral coelom has been emphasized[1], nothing tangible is known of their function. Amoebocytes and what appears to be secretion are found in them, but it is not clear in which direction they are passing. Initially, therefore, their openings were examined to see whether inward or outward currents could be detected.

Ciliary currents. Finely powdered carmine, sprayed from a fine pipette on to an excised axial organ of *Arbacia* examined in sea water, was quickly swept off by the powerful surface ciliation. The external openings of the peripheral canals were readily identified, but no inward or outward currents were detected, even when particles were sprayed directly into the openings. A powerful swirl of particles was sometimes seen on the outside surface.

Most significantly, however, an internal circulation was seen to occur in the clear peripheral cavities of the organ. This becomes evident when the axial organ is viewed by transmitted light because some of the cavities contain red amoebocytes which are swirled around in a minute whirlpool. The amoebocytes may aggregate so that a more or less compact ball or cyst is produced. When excised and examined alive, a cyst appears to consist of an envelope of red and colourless amoebocytes enclosing similar cells which are disintegrating (Fig. 1).

The rotating cysts, or circulating streams of amoebocytes, do not occur in the 'haemal' spaces but in localized swellings of the complementary system of peripheral spaces which communicate directly with the perivisceral coelom. Such dilated spaces may be termed follicles. Usually no more than two could be detected in a normal axial organ. The internal currents which produce the stream or rotation appear to be localized, for when cysts are displaced by gentle pressure into adjoining regions of the canalicular system, their rotation ceases and is resumed when they are restored to their original locus. Again, follic'es may be temporarily isolated by gently pinching them off with fine forceps, but the internal currents continue. When follicles are excised, however, their currents cease immediately.

It is remarkable that such appearances have not been described before, and so it was suspected that they might be artefacts due to immersion of the excised axial organ in sea water. This is not so, for they appear in excised organs examined in coelomic fluid taken from the same animal.

How the currents within the follicles are produced is unknown. Although they show every sign of being produced by internal ciliation, no such ciliation has yet been found in fixed material. In one case a small clot of coelomocytes that had formed in the coelomic fluid outside one of the follicles began to rotate in the same direction and with the same speed as the stream of amoebocytes within. It is difficult to envisage how this could occur except by the transmission of motion through one of the superficial openings, and this may be correlated with the rotary currents detected on the outside of the organ. Although not impossible, it appears unlikely that the

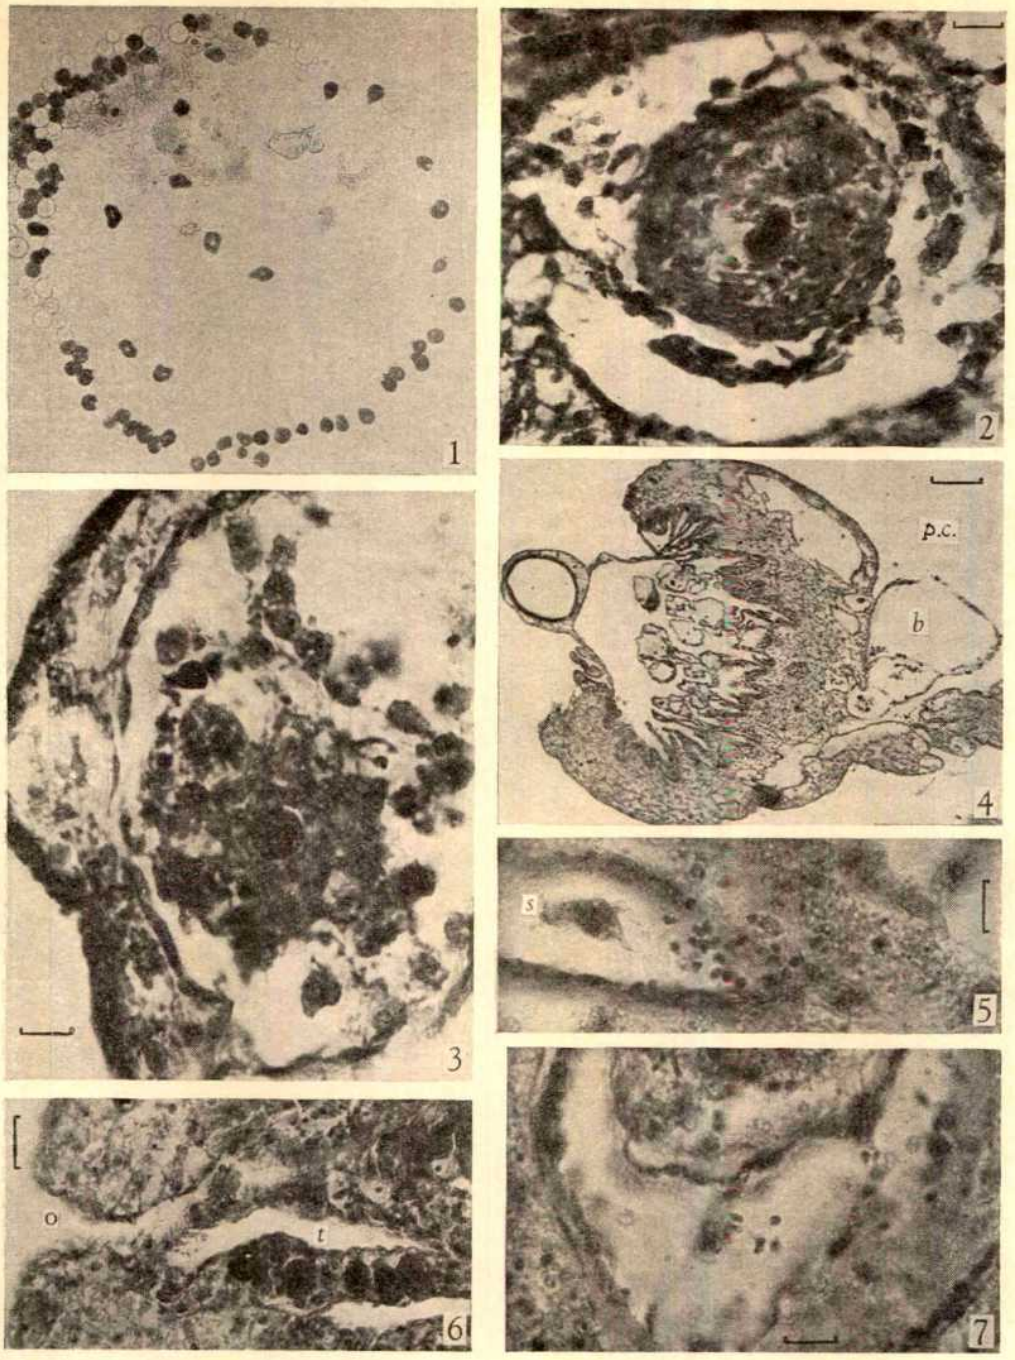

Fig. 1. A living, unstained cyst, excised, while still rotating, from a follicle of the axia organ of *Strongylocentrotus*. The dark bodies are red amoebocytes

Fig. 2. A follicle and its contained cyst in the axial organ of *Strongylocentrotus*, 73 h after part of the perivisceral coelomic fluid had been replaced by coelomic fluid from *Asterias forbesi*. Note the concentric layers of coagulum enclosing coelomocytes and the low flat cells forming the wall of the follicle which has broken down in places. Cells from the wall, together with those from the surrounding haemal space, are invading the follicle. Fixed with Susa in sea water and stained: Mallory. Scale: 13μ

Fig. 3. A follicle and cyst from *Arbacia* 3 days after introducing sperm of the same species into the perivisceral coelom. Note the centre of the cyst, formed of what appears to be compacted sperm heads, surrounded by phagocytes. Fixed and stained as in Fig. 2. Scale: 8μ

Fig. 4. Transverse section of the axial organ of *Arbacia*, 24 h after injecting a culture of *Uronema* with bacteria into the perivisceral coelom. Note the follicle that has distended into thin-walled bladders (*b*), containing amoebocytes and extending freely into the perivisceral coelom (*p.c.*). The bladders appear to have formed successively. No distension of the central lumen is evident in this region. Fixed and stained as in Fig. 2. Scale: 140μ

Fig. 5. A follicle from the same axial organ as that shown in Fig. 3, showing the presence of sperm, some of which (on the right) are free, so that their tails are visible. One sperm cell (*s*) has been ingested by a phagocyte. Fixed and stained as in Fig. 2. Scale: 9μ

Fig. 6. Portion of the axial organ of *Arbacia*, showing a channel within the shaft of cells (*t*), connecting the contractile vessel (on the right) with the peripheral 'haemal' spaces (on the left). The channel is filled with deeply staining amoebocytes. *O*, marks an opening into the perivisceral coelom. Fixed and stained as in Fig. 2. Scale: 20μ

Fig. 7. One of the canals leading from the perivisceral coelom into a follicle of the axial organ of the same urchin as that used in Fig. 3. The dark conical heads of sperm cells, which mostly appear free, can be seen within the canal. Fixed and stained as in Fig. 2. Scale: 8μ

motion is due to the effects of external ciliation spreading into the follicle, because internal currents were often seen below regions where no corresponding external currents could be detected.

Follicular activity appears to be phasic, for follicles were observed in both normal and experimental animals that showed no signs of such activity and contained static cysts. Moreover, the rotation of cysts has been seen to start and stop, lasting for some 30 min.

Experiments with markers. Knowing the phagocytic properties of echinoid amoebocytes, it was suspected that such an elaborate mechanism might be more than merely a means of disposing of effete amoebocytes. Accordingly, cysts were examined following the introduction of identifiable foreign matter into the perivisceral coelom. Initial crude experiments, in which suspensions of indian ink in sea water were injected, revealed nothing in so far as none of the substance appeared in the axial organ. Some was ingested by amoebocytes, but most remained in clots within the perivisceral coelom.

When foreign cells were injected these suspicions were confirmed. Thus when a portion of the coelomic fluid of *Strongylocentrotus* was replaced by an equivalent quantity of coelomic fluid freshly withdrawn from *Asterias forbesi*, examination of stained sections of an organ fixed 73 h later showed the presence in the axial organ of numerous cysts. They consisted of coelomocytes wrapped in coagulum, which appeared to be in concentric or spirally wound layers (Fig. 2), presumably as a result of the continued rotation. Such cysts were found in the central lumen of the organ, but more especially in the peripheral follicles. Comparison with a smear of starfish coelomic fluid, stained in the same way, indicated that many of the cells in the cysts were starfish coelomocytes.

Bearing in mind the difficulty of distinguishing such cells with certainty from some types of the urchin's own coelomocytes, especially after enclosure within a cyst and subsequent fixation, the experiments were repeated using readily identifiable cells. For this purpose, sperm freshly discharged from *Arbacia* was suspended thickly in sea water and a little was mixed with about 2 ml. of coelomic fluid freshly withdrawn from the same individual or from another of the same species. The mixture was quickly injected into the perivisceral coelom of the individual from which the coelomic fluid had been taken. Sections of the axial organ fixed 3 days later showed clearly the presence of sperm in the follicles (Fig. 5) and in the canals opening to the surface (Fig. 7). Some of the sperm appeared to be free; more was enclosed in aggregated amoebocytes which formed cyst-like masses within the follicles (Fig. 3), but most of it appeared in large clots adhering to the outside of the organ.

Such elaborate phagocytosis is frequently accompanied by grosser changes in the axial organ, such as distension of the central and peripheral cavities and stone canal. In *Arbacia*, the effect of sperm was so marked that the dilated peripheral spaces protruded from the surface as large thin-walled bladders. Even more striking were the changes induced by injecting into the perivisceral coelom 0·05–2·0 ml. of a culture of the ciliate *Uronema* with bacteria. Six to 48 h after injection, the axial organ, normally somewhat elongated, had swollen to become almost spherical, its central cavity being enormously dilated, while the peripheral cavities and stone canal had expanded into a crop of large thin-walled bladders (Fig. 4). Both bladders and central cavity showed vigorous circulatory streaming of amoebocytes. These cells sometimes aggregated in the perivisceral coelom in the vicinity of the organ, producing a conspicuous red cloud and in some instances a very obvious quantity of red pigment was deposited in the body cavity, presumably following their dissolution. Similar, but less extensive, changes followed the injection of bacterial culture alone.

The effect of clotting the perivisceral coelomic fluid. The indications of clotting and cell dissolution are suggestive, knowing the marked tendency of echinoid coelomic fluid to respond in this way, following injury, when exposed, or in the presence of foreign bodies[4]. The effect of clotting the coelomic fluid on the axial organ of *Arbacia* was therefore examined. About 2 ml. of perivisceral coelomic fluid were withdrawn into a sterilized hypodermic syringe, in which it clotted rapidly. To assist breakdown of coelomocytes in the clot, the syringe was shaken and in some cases air was briefly bubbled through it. The fluid, together with the clot, was quickly re-introduced into the perivisceral coelom of the same urchin. The effect became clear in 4–10 h. In 'mild' cases the organ was greatly swollen or bore a crop of large or small blisters. In others the whole syndrome appeared, the central cavity of the organ being greatly swollen, the follicles dilated and the blisters expanded into thin-walled bladders. An impressive streaming of amoebocytes was evident in all these cavities.

The specific importance of clotting was shown by repeating the foregoing procedure using a sterilized syringe which had been rinsed with a 10 per cent solution of disodium ethylenediaminetetraacetate in sea water. This inhibited clotting, and the effects on the axial organ of re-introducing coelomic fluid so treated were drastically reduced.

The significance of the reaction. It is clear that the axial organ can take up directly, or ingested in phagocytes, organisms or cells that contaminate the perivisceral fluid and deal with them in an elaborate, well-defined way. The ultimate fate of the cysts and 'foreign' cells has yet to be determined. Similarly, the way in which such extraneous matter enters the organ is unknown, but the presence of the injected cells, both free and ingested in phagocytes, in the canals leading into the organ from the perivisceral coelom, is suggestive. Nevertheless it will be remembered that inward ciliary currents have not yet been detected in these canals. Perhaps the rhythmic pulsations of the contractile vessel are significant in this connexion. Thus the pulsing of 'haemal' fluid through the vessel could exert changing pressures in the periphery of the axial organ and so be indirectly responsible for moving perivisceral fluid in and out of the openings on the surface and the associated system of canals.

Discharge of this decontaminating function is accompanied by equally well-defined overt changes in the axial organ and similar changes are induced by the presence of a clot of the animal's own coelomocytes in its perivisceral fluid. The circumstances are not disparate, in the sense that both are associated with injury. Thus wounds are rapidly invaded by amoebocytes and sealed by a clot formed by the change or breakdown of these cells. At such times invading organisms may enter the tissues or coelomic fluid and their presence in the latter may induce further clotting. The reactions of the axial organ could therefore be part of a defensive injury response in which the organ is 'alerted' or its activity is triggered by 'injury substances' released into the coelomic fluid by the breakdown of amoebocytes; but this has yet to be shown.

In conclusion, two points should be emphasized. The possible reactions of other organs to the experimental conditions described have not been studied, though cursory examination failed to reveal anything so obvious as those of the axial organ. No claim is made that this may be the sole function of the organ.

I thank Dr. G. Holz for cultures of *Uronema* and bacteria, Dr. R. Boolootian and Mr. Z. Podhorodecki for help with photography, and Drs. Boolootian and Farmanfarmaian for advice. I also thank Dr. W. D. Russell-Hunter for providing facilities for the work, which was supported by a grant from the National Science Foundation, *G.B.*-3447, made to the Department of Invertebrate Zoology of the Marine Biological Laboratory.

FOUR SIBLING SPECIES INCLUDED IN *Simulium damnosum* THEOBALD (DIPTERA : SIMULIIDAE) FROM UGANDA

By Dr. R. W. DUNBAR*
Department of Zoology, University of Durham, South Road, Durham

THE black fly *Simulium damnosum* was described in 1903 by F. V. Theobald from material he collected in the Nile provinces of Uganda[1]. The name he chose, *damnosum*, reflects an opinion of the fly's voracious biting habits. In 1923, in Sierra Leone, on the other side of Africa, D. B. Blacklock identified *S. damnosum* as a vector of the filarial worm *Onchocerca volvulus* which produces in man the disease onchocerciasis, or 'river blindness'[2]. As the seriousness and widespread occurrence of this disease became apparent it was realized that this black fly was the most important vector of onchocerciasis. The habits of this fly have since been extensively studied in the hope of eliminating it and controlling the disease. From these investigations one point stands out, the extreme variability of its habits[3]. For example, in some areas the fly bites man at low altitudes but not at higher altitudes; in different regions the reverse situation seems to be true. On the Nile River larvae may be found at the brink of a waterfall or in quiet backwaters where the only movement is wave motion[3]. Because of this variability several field workers have begun to suspect that more than one species is involved[4]. Yet morphological variations between specimens from widely distributed localities are so slight that most taxonomists have considered *S. damnosum* to be a single species. One possible way of resolving whether or not *S. damnosum* is one or more species is to use the technique which has been successful in solving similar Holarctic black fly problems, the examination of the larval salivary gland giant polytene chromosomes[5–7]. In these insects they are large and often very clear (Fig. 2). This article describes how such a cytotaxonomic survey of larvae from Uganda, identified as *S. damnosum*, disclosed the presence of four distinct cytological categories.

In an ideal species, one which has only one giant chromosome banding pattern, all the individuals will share this pattern. The most frequent alterations to this standard pattern are two-break rearrangements in which the interstitial segment becomes inverted. Such inverted segments are called 'inversions'. Within a species these inverted and original sequences can be expected in homologous chromosome pairs in any of three ways: both chromosomes having either (1) the standard sequence or (2) the inverted sequence (the two alternate 'homozygous' arrangements), or (3) one chromosome being standard and the other inverted (the 'heterozygous' arrangement). The finding of this last category, the heterozygote, establishes that an inversion is part of the chromosomal polymorphism of a species, that is, it is an intraspecific ('floating') inversion[5]. Species have usually a few to many floating inversions.

When the banding patterns of closely related species are examined there are almost always, in black flies, one or two inverted sections which appear to be like the two alternate homozygous arrangements already mentioned. However, the intermediate heterozygous arrangement is never found. The best interpretation for this is that there are two non-interbreeding populations, that is, two species. These interspecific ('fixed') inversions are the main evidence for the establishment of the cytological categories which are characteristic of different species[5]. Secondary evidence for these categories comes from the floating inversions in that two species rarely share a floating inversion, although this is theoretically possible. In practical terms a floating inversion can be assigned to one specific category. Cytotaxonomic identification of a species is not dependent on variable (or in black flies, almost invariable!) morphological characters, but is dependent on the observation of the chromosomal banding pattern which undergoes virtually no phylogenetic change except by clearly defined, discrete steps, such as inversions. Precise cytological categories, therefore, are provided by the presence or absence of inversions.

There are also micromorphological characters in the chromosomes which are very useful in the identification of a species, a chromosome or even a chromosome arm. Most of these are prominent features within the banding pattern and have been given descriptive names (Figs. 1 and 2). Although their expression may vary, the real value of these characters is in their relative positions within the banding pattern where they serve as ready markers. Other micromorphological characters[8] include the chromosome number, the degree of pairing of homologous chromosomes, the expanded regions associated with centromeres and the degree of fusion, if any, of the centromeres.

The material used in this investigation came from three localities: (1) Sebwe River, Toro (Ruwenzori); (2) Nile River, Kagela Falls, 14 miles downstream from Jinja; (3) Kagagala River, near Kikagati, Kyansore Island, Ankole (Table 1). The larvae were

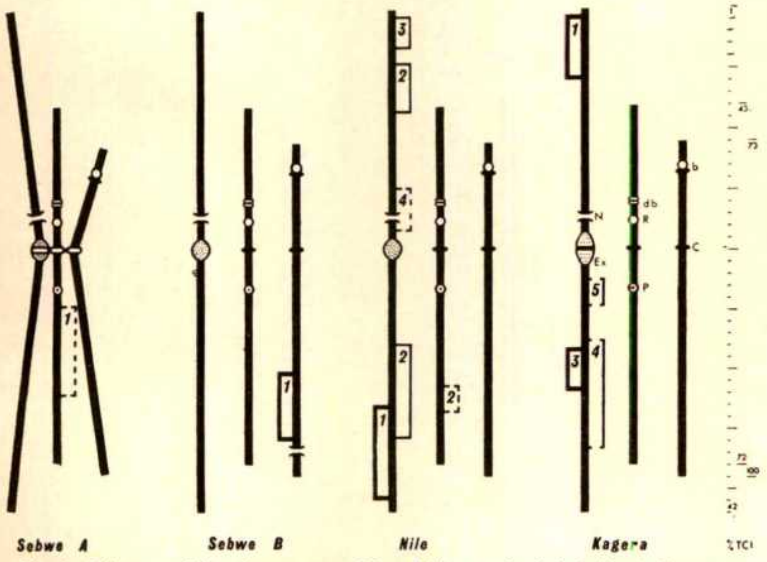

Fig. 1. Idiograms of the chromosomes of four sibling species included in *S. damnosum*. The inversions and chromosomal features are plotted according to their percentage position in the total complement length (percentage TCL). Brackets indicate inversions. Heavy brackets to the left represent interspecific inversions. Brackets to the right represent floating inversions; solid brackets, common floating inversions (more than 40 per cent heterozygotes); broken ones, uncommon floating inversions (less than 4 per cent heterozygotes); detached brackets, inversions restricted to *Y* chromosomes. *C*, Centromere (ref. 8); *N*, nucleolus (ref. 8). Descriptive names: *b*, 'blister' (ref. 13); *db*, 'double bubble' (refs. 7 and 14, 'bulge'); *R*, 'ring of Balbiani' (refs. 8 and 14); *P*, 'para-Balbiani' (ref. 6); *Ex*, 'expanded region' associated with centromere (ref. 8)

* Present address: Division of Natural Sciences, University of Saskatchewan, Regina, Canada.

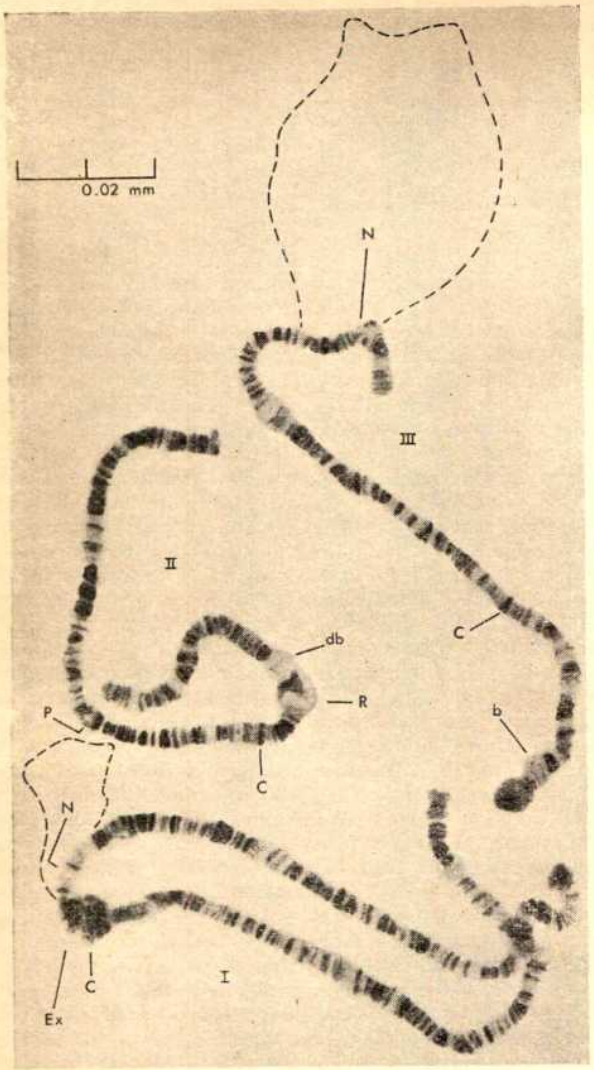

Fig. 2. Giant chromosomes of 'Sebwe *B*' (No. 1693.63). Broken lines show the outlines of the nucleolar masses

fixed in Carnoy's fixative, stained in leucobasic fuchsin, and the slides made permanent by the dry ice method[5,8,9]. A modified Leitz 'Ortholux-Orthomat' microscope–camera combination was used for analysis and photo-micrography. A photographic map was made of the chromosomes of a specimen (No. 1693.63) from the Sebwe River (henceforth referred to as 'Sebwe *B*'). All the slides were compared with this map. The four siblings were provisionally named after the rivers from which they came. They are identified as 'Sebwe *A*', 'Sebwe *B*', 'Nile' and 'Kagera'. The details of this analysis are summarized in the idiograms (Fig. 1) which depict graphically the features of the cytological categories to be described. The inversions and the micromorphological characters have been located by plotting their percentage positions within the total complement length.

The close relationship of these four siblings is shown by the basic similarities of their chromosomes. All four have three pairs of tightly paired chromosomes, and arm-length ratios about the centromeres of 1 : 1·1, 1 : 1·5 and 1 : 1·7. They share the same basic banding pattern except for the few interspecific inversions. They have the same relative positions for the main nucleolus and the micromorphological characters of the second and third chromosomes. In these siblings only the first chromosome has an expanded region associated with the centromere. The centromeres of the other two chromosomes are indistinguishable from a large band.

Table 1. Collections of *S. damnosum* Complex and the Number of Slides of Each Sibling Analysed

Location:	Sebwe River		Nile River		Kagera River		Total
Date:	31/1/63	10/3/63	28/3/64	8/4/65	10/3/63	11/4/64	
Sibling							
Sebwe *A*	11	25					36
Sebwe *B*	8	23					31
Nile			27	20			47
Kagera					4	44	48

Sebwe *A* was chosen, because of its phylogenetically central position, as the basis for comparisons (Fig. 3). Its banding pattern, therefore, is the standard against which the others are compared. This is almost a chromosomally monomorphic species since only a single heterozygous inversion configuration was found. It is in the second chromosome (No. II), short arm (*S*) and was the first inversion in any sibling found in that arm; it is inversion II*S*-1. Another feature of this sibling is that the centromeres are tightly fused, but no chromocentre is formed. The centromeres also appear 'glassy' rather than dark as in the other siblings.

Sebwe *B* differs from Sebwe *A* by a single interspecific inversion in the third chromosome, III*L*-1. This appears to be a monomorphic species since no floating inversions were found. Sebwe *B* has a second nucleolar organizer in the third chromosome distal to III*L*-1, the only sibling with this feature.

Nile differs from Sebwe *A* by a single interspecific inversion in the first chromosome, I*L*-1. This is a relatively polymorphic species with four floating inversions in the first chromosome, three of which are common, and one in the second chromosome, I*S*-2, I*S*-3, I*S*-4, I*L*-2 and II*L*-2.

Kagera differs from Sebwe *A* by two interspecific inversions in the first chromosome, I*S*-1 and I*L*-3. The only two floating inversions, I*L*-4 and I*L*-5, were always found heterozygously, together and only in males. Therefore this sibling has a distinct *X* chromosome with I*S*-1 and I*L*-3, and a distinct *Y* chromosome with I*S*-1, I*L*-3·4 and I*L*-5. It is the only sibling in which the *X* and *Y* chromosomes can be distinguished. The expanded region is slightly larger than in the other three siblings and has a distinct band marking the centromere.

Interspecific inversions not only define cytological categories, but they also show phylogenetic relationships[5]. If the interspecific differences between Sebwe *A* and the other three are plotted as in Fig. 3, then to find the difference between any peripheral pair it is only necessary to 'add' the inversions along the lines. Thus, for example, the difference between Sebwe *B* and Kagera is three interspecific inversions, I*S*-1, I*L*-3 and III*L*-1. This is precisely what is found. Unfortunately without further information it is impossible to determine phylogenetic direction[10].

Sebwe *A* and Sebwe *B*, because they are sympatric, are clearly a pair of species, and Sebwe *B*, because of its position in the phylogenetic scheme, is a species distinct from the others. However, there is a lack of evidence to eliminate entirely all possible arguments that certain of the remaining three siblings represent isolated populations of the same species[5]. The distance between the Sebwe and Kagera Rivers is less than 100 miles, and there is a little more than 100 miles between the Sebwe and Nile Rivers. With probable breeding sites for any of these siblings in the intervening areas, and considering the flight range of these insects, it is practically impossible that such large cytological differences could represent geographic variants of the same, but widespread, species

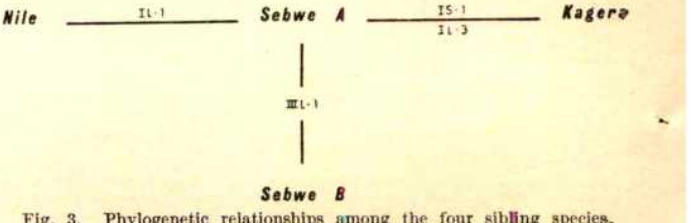

Fig. 3. Phylogenetic relationships among the four sibling species. Interspecific inversions are shown between the siblings

around Lake Victoria. These doubts could be dispelled by the examination of intermediate populations and the establishment of ranges for each sibling.

It is a reasonable conclusion, therefore, that these four siblings, Sebwe *A*, Sebwe *B*, Nile and Kagera, represent four distinct but closely related species. The sibling identified here as Nile may be *S. damnosum* since the type locality is the 'Jinja fly belt' at the mouth of the Nile. It also raises the possibility that some of Enderlein's names for species in this group may be valid[11,12].

Complete chromosome maps for these four species will be published at a later date. It is also hoped that for this future report it will be possible to examine materials of the *S. damnosum* complex from other parts of Africa.

I thank A. W. R. McCrae and M. A. Prentice of the Ministry of Health, Vector Control Division, Kampala, Uganda, for contributing all the larvae examined. This work was supported by the Department of Technical Co-operation Scheme *R*1374 obtained through the diligence of Prof. W. E. Kerskaw of the Liverpool School of Tropical Medicine.

PLANARIANS AND MEMORY

By Prof. ALLAN L. JACOBSON, CLIFFORD FRIED and SHELDON D. HOROWITZ
Department of Psychology, University of California, Los Angeles

I. Transfer of Learning by Injection of Ribonucleic Acid

SEVERAL recent investigations of planarians have contributed suggestive evidence regarding the biochemical basis of memory. McConnell[1] and John[2] found that cannibal worms which had ingested classically conditioned worms later performed better than did cannibals which had ingested untrained worms. Corning and John[3] obtained evidence that ribonuclease may 'wipe out' conditioning in regenerating planarians. Two preliminary reports[4] have indicated that injection of ribonucleic acid (RNA) extracted from trained planarians may enhance responding in untrained planarians.

Two related factors have delayed full acceptance of these findings: the controversy concerning the validity of classical conditioning in planarians, and the absence of pseudo-conditioning controls in several of the aforementioned investigations (for discussion of these problems, see ref. 5). The experiment described here was carried out in an attempt to resolve these questions, at least in part, by showing that (*a*) classical conditioning effects can be easily distinguished from pseudo-conditioning effects in planarians, and (*b*) enhanced responding is produced by injection of RNA from classically conditioned but not from pseudo-conditioned or non-conditioned planarians.

675 planarians (*Dugesia dorotocephala*) of about 1 cm length were used, which had been obtained from West Coast Biological Supply Co., Los Angeles. They were maintained and trained in spring water and were not fed during the course of the experiment (the composition of the water, as provided by the laboratory of Sparkletts Drinking Water Corp., was 30 mg/l. calcium, 15 mg/l. sodium, 72 mg/l. chlorine, 12–14 mg/l. bicarbonate, 25 mg/l. silica, and 0·1 mg/l. fluorine). The planarians were handled with a sable brush. The room light was diffused and was on only during the day.

The planarians were trained in a rectangular plastic trough measuring 14·5 cm × 5·5 cm × 5·5 cm and filled with spring water to a depth of 1·5 cm. Aluminium plates which covered the two long walls of the trough served as electrodes. A potential of 10 V peak 60-c/s a.c. was connected to the electrodes by a clock device. Current flow through the volume of water was 2·5 m.amp peak. The conditioned stimulus (CS) was provided by a 75-W bulb in a 25-cm reflector suspended 22 cm above the trough. A piece of paper covered the reflector and diffused the light. The illumination at the trough measured 13 ft.-candles with the CS-light off and 400 ft.-candles with the CS-light on. All stimulus and interval durations were controlled by Hunter clocks.

Three groups of 200 planarians each were used in the first stage of the experiment. One group (non-conditioned, hereafter referred to as group NC) was simply permitted to rest in their home containers. A second group (classically conditioned, or CC) was given training consisting of paired presentations of light and shock. Before these training trials were undertaken, group CC was given fifty 3-sec presentations of light alone in two sets of twenty-five trials separated by a 10-min interval. The interval between light presentations within a set was 20 sec. Then, following another 10-min interval, training was instituted. A training trial consisted of a 3-sec presentation of light, during the last second of which the shock was also applied. The inter-trial interval was 20 sec. On the first day of training, group CC received two sets of twenty-five conditioning trials, with 10-min intervals between adjacent sets, in addition to the fifty light-alone trials. On the next day, group CC received three further sets of training trials.

The third group (pseudo-conditioned, or PC) was trained in the same fashion as was group CC, except that for group PC light and shock were presented in a fixed interspersed sequence, rather than being paired. Whereas group CC received one light-shock pairing every 20 sec, group PC received a stimulus, either light or shock, every 10 sec. The total number of lights and shocks received by group PC in a given trial set was equated to that for group CC, and shock was never given to group PC more than twice in succession. At the beginning of each day's sessions, all worms were adapted to the trough for 10 min before training was commenced.

On each presentation of light, each worm in groups PC and CC was scored according to whether or not it responded during the first 2 sec. A response was defined as a discernible longitudinal contraction of the body, this being the unconditioned response to shock. Other changes in locomotion, including stopping, or lifting, wagging, or turning the head, were not counted as responses. On eight separate occasions, two observers made independent judgments on a set of twenty-five trials. Agreement ranged from 23 out of 25 to 25 out of 25; overall, the two judges agreed on 192 out of 200 trials.

Twenty conditioned and twenty pseudo-conditioned worms (randomly selected) were scored individually for

the fifty light trials and 125 subsequent training trials. The performance levels of these animals are presented in Fig. 1. The differentiation between the two groups in their responsiveness to light is apparent and is further indicated by the ranges of scores for the last two training sets: on set 4, the range for CC was 10–17, that for PC 0–5; on set 5, the range for CC was 13–17, that for PC 0–6.

An additional five sets of trials were given to groups CC and PC, three sets on the day preceding extraction (described below) and a final two sets on the day of extraction. During the last trial set, four worms from each of the groups were scored individually. The four CC worms scored 14, 15, 16, 17; the four PC worms scored 1, 2, 3, 3.

After the completion of training, RNA was extracted from each of the three groups of planarians by a phenol-extraction technique (for details of the procedure, see ref. 6). The 200 worms of a given group were pooled together for an extraction. The RNA from each group was dissolved in 700 μl. of isotonic saline. The amount of RNA was determined from the optical density at 260 mμ (ε^p = 7,450 in 0·2 M sodium chloride). One extract was used for the determination. The yield was approximately 3·4 mg/1·0 g of tissue. During the extractions, the experimenters did not know the identity of any group.

Four hours after extraction, the RNA from each of the groups (NC, PC and CC) was injected into twenty-five untrained planarians. Fourteen hours before injection began, each of these 75 recipient worms had been given 100 light-adaptation trials, in two sets of fifty trials separated by a 10-min interval. The inter-stimulus interval within a set was 20 sec. The injections were performed under a binocular dissecting microscope in the following manner: a metal cap was filled with paraffin, and a depression approximately the size of a planarian was cut into the paraffin. The metal cap was placed in a Petri dish and the latter was placed in a container of dry ice. A planarian was placed in the depression. Within 1 min the low temperature resulted in the planarian becoming quiescent. When this was so, 20 μl. of the appropriate solution was injected into the body cavity by way of the pharynx. A 100-μl. No. 710 Hamilton syringe with a 1·3 cm 30-gauge needle was used, and a finely drawn-out capillary tube was glued to the needle. The capillary tube was replaced as necessary during the injections. Like the extractions, the injections were conducted in 'blind' fashion; that is, the research worker carrying out the injections did not know to which group the planarian which he was treating belonged.

Twenty-four hours after the injections had been completed, the 75 injected worms were tested individually. Each worm received twenty-five presentations of light alone, spaced 20 sec apart, and responses occurring during the first 2 sec of the light were recorded. No shock was ever given during testing. Again, all testing was conducted 'blind'.

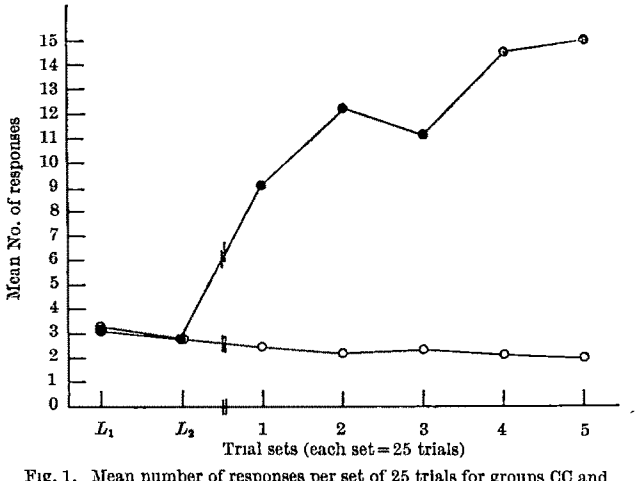

Fig. 1. Mean number of responses per set of 25 trials for groups CC and PC. On the abscissa, L_1 and L_2 are sets in which light alone was presented, and 1–5 represent training sets. ●, CC (N = 20), ○, PC (N = 20)

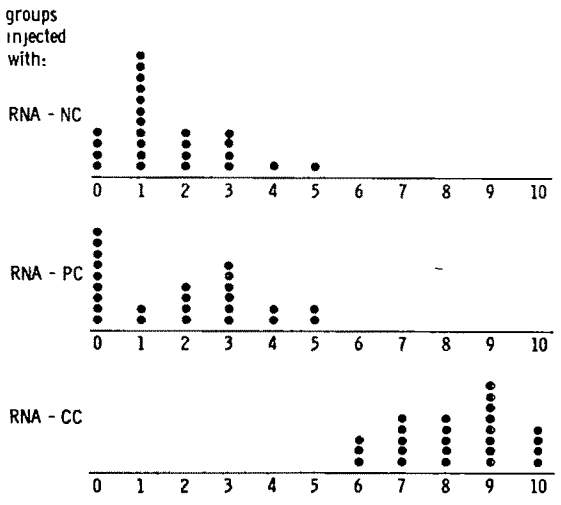

Fig. 2. Distribution of scores (responses per 25 trials) for injected planarians

Fig. 2 presents the number of responses made by each worm in the test series. The mean for planarians injected with RNA from group CC was 8·2, that for the 'PC-injected' group was 1·8, and that for the NC-injected group was 1·6. By a Mann–Whitney U test[7], the group injected with RNA from classically conditioned worms was superior in performance to either of the other injected groups ($P < 0·001$). As Fig. 2 shows, the ranges of the two control groups, on one hand, and of the experimental group, on the other, did not overlap.

Several conclusions can be drawn from this experiment: First, classical conditioning in planarians is a distinct and valid phenomenon, and pseudo-conditioning effects, at least under the present conditions, are negligible. This finding corroborates that of Baxter and Kimmel[8], but in the present experiment the differences between groups were much more pronounced. Secondly, injection of the RNA preparation from group CC was sufficient to induce responsiveness to the light which could not be accounted for on the basis of nutrition, handling, or stimulation received by the donor group. Rather, the critical feature for both the conditioning effect and the RNA transfer effect was apparently the contiguity between the stimuli (light and shock). Since such contiguity is generally considered to be the defining characteristic of 'true' conditioning, the present data would seem to suggest that a specific learned response was transferred by way of the injection of the RNA preparation. This conclusion is strengthened by the fact that no shock was used during testing, and thus no new learning could have occurred.

We have conducted two supplementary experiments designed to ascertain whether RNA was in fact the effective transfer agent: (1) RNA extracted from CC and PC groups by the phenol method as previously described was further purified by 'Sephadex' chromatography (*G*-50 coarse beaded form; 1 mM magnesium acetate 5 mM *tris*-acetate, *p*H 7·2) and methylated albumin chromatography (step-by-step elution with 2·0 M sodium chloride, 0·05 sodium phosphate, *p*H 6·7). A significant difference in the levels of response was found between the two groups injected with these purified preparations (mean of experimentals, 7·8; mean of controls, 2·9; $P < 0·001$). (2) RNA from CC animals was degraded by treatment with 0·3 N sodium hydroxide (16 h at 37° C). Recipients (group 2) of this degraded RNA performed at about the same level as did recipients (group 3) of RNA from PC animals, and both were significantly lower in performance than recipients (group 1) of RNA from CC animals (mean of group 1, 8·4; mean of group 2, 4·7; mean of group 3,

5·7; group 1 versus group 3: $P < 0.01$; group 1 versus group 2: $P < 0.001$).

II. The Influence of Prior Extinction on the Ribonucleic Acid Transfer Effect

A NUMBER of experiments, including the preceding article, appear to implicate RNA in memory functions. The most prevalent approaches attempt either to correlate RNA changes with a learning experience[1], or to transfer behavioural tendencies from one organism to another by injection of RNA[2]. These experiments and the relevant theory generally concern the acquisition (learning) of new behaviour patterns. Any adequate biochemical concepts of memory must also, however, account for the diminution or loss of learned behaviours which typically occurs in experimental extinction. Proponents of the RNA hypothesis might adopt either of two positions on this point: (*A*) experimental extinction acts to modify (either directly or indirectly) the RNA which was (hypothetically) modified during acquisition; or (*B*) experimental extinction results in behavioural decrements by some mechanism which does not involve changes in RNA. The latter position implies that any modifications in RNA produced during acquisition persist during and after extinction.

The present experiment attempts to assess these two hypotheses. As in the investigation described in the preceding article, one group of planarians was classically conditioned and a second group was pseudo-conditioned. A third group was classically conditioned and then experimentally 'extinguished' by repeatedly presenting the conditioned stimulus (CS) alone. RNA extracted from each of these three groups was injected into naïve planarians. Hypothesis *A* would predict that the group receiving RNA from 'extinguished' worms should be comparable in performance to the group receiving RNA from pseudo-conditioned worms; hypothesis *B* would predict that the group receiving RNA from 'extinguished' worms should be comparable with the group receiving RNA from classically conditioned worms.

Initially, 400 worms received classical conditioning trials with paired light and shock, and 200 worms received pseudo-conditioning trials with unpaired light and shock. The procedures followed those described in the preceding article: fifty exposures to light alone were followed by 250 training trials in sets of 25 trials. Four animals randomly selected from each group were observed individually during the last 25 trials: those from the CC group scored 11, 13, 13, 13; those from the PC group scored 0, 1, 3, 4.

The classically conditioned group was then divided into two equal groups. One of these groups (CCE) was given 200 presentations of light alone at 20-sec intervals, and a second session of 50 light-alone trials after a 1-h break. The other conditioned group (CC) and the pseudo-conditioned group (PC) were equated to group CCE in terms of handling and apparatus exposure—that is, these groups were placed in the apparatus but were not given presentations of light. Four animals selected at random from each

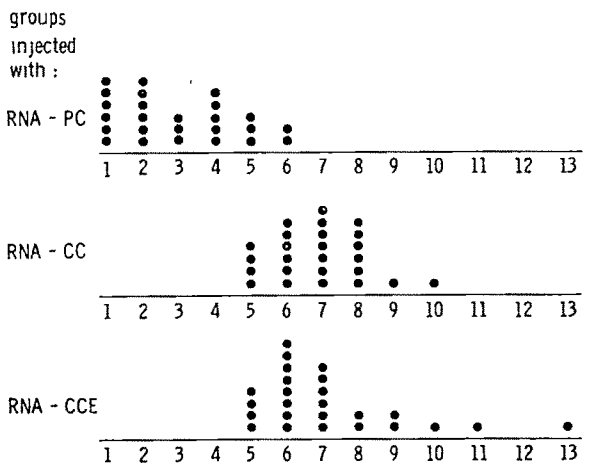

Fig. 1. Distribution of scores (responses per 25 trials) for injected planarians

of the three groups were then tested for 25 trials: CC animals scored 10, 11, 13, 13; PC animals scored 1, 2, 5, 5; and CCE animals scored 1, 2, 2, 5.

RNA was then extracted (in blind fashion) from groups CC, PC and CCE by the phenol method as previously described and was further purified by 'Sephadex' chromatography (*G*-50 coarse beaded form; 1 mM magnesium acetate, 5 mM *tris*-acetate, *p*H 7·2). The RNA extracted from each of the three groups was injected into 25 naive planarians which had previously been given 100 presentations of light alone. Each animal received 25 µl. of the RNA preparation. Injections were performed in blind fashion. Twenty-four hours later, each injected animal was given 25 presentations of light alone and was scored for number of responses (contractions). This testing was 'blind', and animals from the three groups were taken in a randomly interspersed order.

Fig. 1 presents the number of responses made by each worm on the test series. The mean for planarians injected with RNA from group CC was 6·9, that for worms injected with RNA from group CCE was 7·2, and that for worms injected with RNA from group PC was 3·0. The medians were, respectively, 7, 7, and 3. By a Mann-Whitney *U* test[3], the group injected with RNA from PC worms differed markedly from each of the other two injected groups ($P < 0.001$). The latter two groups clearly did not differ.

Thus, the effects on naïve recipients of RNA from extinguished planarians were indistinguishable from the effects produced by RNA from conditioned planarians. One possible interpretation of these data is that spontaneous recovery might account for the level of response of the group injected with RNA from group CCE. Some subsidiary data force us to reject this possibility: five worms from group CCE were put aside following conditioning and subsequent extinction and were then given 25 test trials at the time that testing of the injected animals was conducted. The scores obtained were: 0, 1, 1, 1, 2. Clearly there was no spontaneous recovery of the conditioned response. In addition to substantiating our earlier findings, these results, then, suggest that experimental 'extinction', while abolishing the conditioned response in planarians, did not affect the RNA of the conditioned animals.

LETTERS TO THE EDITOR

ASTRONOMY

Transient Lunar Events: Possible Causes

In a recent communication[1], E. J. Flamm and R. E. Lingenfelter discussed the nature of luminescence and of lunar bright spots. They found that of nineteen reported bright spots in the region of Aristarchus, most occurred during years when the sunspot numbers were low, and they stated: "Clearly the 19 events are negatively correlated with solar activity". The Moon possesses only a negligible magnetic field and the particle flux at the Moon is, as pointed out by Flamm and Lingenfelter, too small by orders of magnitude to excite fluorescence, no matter whether flares, the solar wind, or cosmic-ray flux is invoked. A 'negative' correlation with sunspot number, if interpreted as a negative (or inverse) correlation with solar activity generally, implies a connexion with magnetic phenomena just as surely as a positive or direct correlation and would be just as hard to explain.

I analysed the same events with respect to monthly sunspot number, and also the distribution of sunspot numbers from 1749 to 1964 in the groups 0–30, etc., which were selected by Flamm and Lingenfelter for their survey. In addition, reports of a total of 103 events occurring in a number of areas of the Moon between 1749 and 1963 were collected by Mrs. Jayley Burley and me[2] and have also been grouped by sunspot number (see Table 1). The run of the three sets of statistics was quite similar, and my conclusion is that, contrary to Flamm and Lingenfelter's finding, no correlation of lunar events with sunspot numbers exists, and that the excess of lunar events during periods of low sunspot numbers is found because sunspot numbers are generally low. In the present survey, monthly means were used rather than yearly means.

Monthly sunspot relative numbers were available[3] for all months from January 1749 to June 1964. A few events for dates (even one naked-eye observation of 1587) earlier than this were included in Mrs. Burley's and my compilation, but could not be used here because monthly sunspot numbers were not available before 1749. Similarly, five reports within the past year have been omitted because sunspot reports for this period have not yet reached our library. The period 1749–1964 includes 2,586 months, and random fluctuations can be expected to be smoothed out.

When the data in the last two columns of Table 1 are plotted on a histogram, the tops of the columns run very smoothly. The curves for the other two smaller sets of data are not so smooth, as would be expected, but the trend is the same and the deviations from the same mean curve are consistent with the error law, so that no special selection effect or correlation seems to be present. The data for Aristarchus do not appear to be different in kind from those for other locations such as Alphonsus, Plato, Mare Crisium and other lunar features for which records of events recur repeatedly in the literature. There thus does not seem any reason for singling out the Aristarchus events and I have not done so here.

Table 1. Records of Lunar Events according to Monthly Sunspot Relative Numbers

Monthly mean Sunspot No	(Aristarchus E J.F and R.E L.) No. of events	%	(All available, J.B and B M M.) No. of events	%	All months Jan. 1749–June 1964 No of months	%
0 to 30 0	13	59 1	37	35 9	1,064	41 1
30+ to 60·0	4	18·2	26	25 2	691	26·7
60+ to 90 0	1	4 5	20	19 4	423	16·4
90+ to 120 0	1	4·5	8	7·8	220	8·5
120+ to 150·0	3	13·6	3	2 9	109	4·2
150+ to 180 0	0	0	5	4 8	52	2 0
180+ to 210·0	0	0	2	1 9	21	<1
210+ to 240·0	0	0	1	<1	5	<1
240+ to 270 0	0	0	1	<1	1	<1
Total	22	99 9	103	100 0	2,586	100·0

The statistics of Table 1 would seem to represent a random distribution of events superposed on an asymmetric distribution of sunspot numbers, indicating that no correlation exists and that we need to look further for a cause. There are indications that internal lunar causes have been[4] and still may be significant and that lunar events may be initiated by tidal cracking (near perigee—the corresponding time on Earth is high tide) or at periods of maximal crustal relaxation (near apogee, which corresponds to low tide on the Earth) with consequent release of hot or cold gases[5–7].

PHYSICS

Entropy and Gravitation

The application of the second law of thermodynamics to bodies interacting through gravitational forces has been the subject of much controversy and discussion (see, for example, Kurth's *Mechanics of Stellar Systems*[1]). A purely phenomenological discussion of such a problem is unlikely to provide an answer to this problem and it is therefore important to consider it from the point of view of statistical physics.

The remarkable series of papers by Chandrasekhar on the "Statistics of the Gravitational Field arising from a Random Distribution of Stars"[2a–e] has shown that the main conclusions of the classical theory of Brownian motion, including the approach to equilibrium, may be applied to gravitational interaction. However, as noticed by Chandrasekhar[2], there remained a difficulty due to the slow decay of the force autocorrelation function with time, which leads to a long-distance divergence in the Fokker–Planck type of equation. For plasmas this divergence can easily be eliminated by taking into account screening, but for gravitation the question remains unsolved.

In order to discuss in greater depth the physical implications of this divergence, let us start with the general evolution equation for the velocity distribution function ρ_0 of a classical N-body system (see Prigogine, *Non-Equilibrium Statistical Mechanics*[3]). This equation may be written:

$$\frac{\partial \rho_0}{\partial t} = \int_0^t d\tau G(\tau)\ \rho_0(t-\tau) + F(t) \qquad (1)$$

It has two important features: (*a*) the collision operator $G(\tau)$ has a 'non-Markoffian' character due to the finite duration of the collision; (*b*) the memory of the initial correlations appears through the destruction fragment

$F(t)$. When both effects are neglected we recover, in the limit of weak coupling or small concentration, the usual Boltzmann (or Fokker–Planck) equation. Boltzmann's theorem then follows directly.

It is essential, however, to notice that the H-theorem follows not from the general equation (1) but from its Boltzmann's 'approximation'.

Let us call $\psi(z)$ the Laplace transform of the collision operator $G(\tau)$. The non-Markoffian equation (1) can also be written:

$$\frac{\partial \rho_0}{\partial t} = \psi\left(i\frac{\partial}{\partial t}\right)\rho_0 + F(t) \qquad (2)$$

while its Boltzmannian approximation is:

$$\frac{\partial \rho_0}{\partial t} = \psi(0)\,\rho_0 \qquad (3)$$

The difficulty with gravitational interaction is that $\psi(z)$ has now for $z \to 0$ a logarithmic singularity which can no more be eliminated through a summation of classes of events as in the electromagnetic plasma case (see Balescu, ref. 4).

The study of gravitational plasmas has therefore to start with equations of type (2) and not with their Boltzmannian approximation (3). For rather similar reasons the destruction fragment $F(t)$ can no more be neglected in (2) (see Prigogine and Résibois, ref. 5).

Detailed results will be reported soon by G. Severne and myself in *Physica*. The main conclusion is that the evolution of the system now involves a succession of incomplete collisions: because of their long duration a new collision begins before the preceding one is achieved. The result is not only a randomization of kinetic energy but also a transformation of gravitational energy into thermal energy. A Boltzmann type H quantity can be defined, of course, but its time derivative (even in a coarse-grained sense) has no well-defined sign. It seems, therefore, that the existence of a large number of interacting degrees of freedom is not a sufficient condition for the existence of entropy; conditions on the forces are also necessary (such that $\psi(z)$ for $z \to 0$ is finite). Of course, the canonical distribution is still a time independent solution of the kinetic equation (2), but the system has no mechanism to reach it if it is not imposed at the initial time. Phenomenological thermodynamics seems to be applicable only to short range (or electromagnetic) forces for a given state of gravitational bodies. If, on the other hand, gravitation is included, there seems to be no way to order the states of a galactic system (or *a fortiori* of the universe) according to the value of the entropy.

Most of this work was performed while I was staying at the Research Laboratories, General Motors Corporation, Warren, Michigan. I thank Dr. R. Herman for many stimulating discussions.

Holography and its Crystallographic Equivalent

Recent advances in holography[1] have made apparent certain formal relationships between optical image synthesis, on one hand, and the heavy atom technique in X-ray crystallography, on the other. Bragg[2] has already qualitatively indicated this analogy. An exact correspondence between the two processes has become clear only since the following two developments: (i) Fourier transform holography for extended sources[3]; (ii) the Ramachandran and Raman[4] α-synthesis to deconvolute the Patterson function when the structure is partially known.

In the case of holography, we perform an interference experiment between the known and unknown extended objects $T_P(\xi)$ and $T_Q(\xi)$, where these symbols define the complex amplitude transmission of the electric field vector distribution on illumination by a wave of unit amplitude. Thus the complex amplitude distribution at point x on the hologram will be $A(x) = t_P(x) + t_Q(x)e^{2\pi i a\,x}$, where $t_P(x)$ and $t_Q(x)$ are the spatial Fourier transforms of $T_P(\xi)$ and $T_Q(\xi)$ and a is the separation of $T_P(\xi)$ and $T_Q(\xi)$, that is:

$$t(x) = \int T(\xi)e^{2\pi i x\,\xi}\,d\xi$$

where the integral is taken over the surface of the source. The intensity $H(x)$ recorded on the hologram at point x will then be:

$$\begin{aligned} H(x) &= A(x).A^*(x) \\ &= |t_P(x)|^2 + |t_Q(x)|^2 + t_P(x).t_Q{}^*(x)e^{-2\pi i a.x} \\ &\qquad + t_P{}^*(x).t_Q(x)e^{2\pi i a.x} \end{aligned}$$

It was shown by Stroke *et al.*[3] that a Fourier transformation would permit the reconstruction of the unknown object, $T_Q(\xi)$, provided that the hologram were illuminated by the same object $T_P(\xi)$ and that the Fourier transform of the product $t_P(x)t_P{}^*(x)$ be a delta function. Further, if it is desired to remove the two centrosymmetrically related images, it is necessary that $t_P(x)t_P(x)$ is not a delta function. It follows that the reconstructed object will be formed by the transform of:

$$\begin{aligned} t_P(x)|t_P(x)|^2 + t_P(x)|t_Q(x)|^2 + t_P(x).t_P(x)\,t_Q{}^*(x)\,e^{-2\pi i a\,x} \\ + t_P(x).t_P{}^*(x)\,t_Q(x)\,e^{2\pi i a.x} \end{aligned} \qquad (1)$$

In the case of a partially known crystallographic structure we observe the interference effect between the known and unknown parts of the structure. The complex amplitude F_H of the resultant wave will then be:

$$F_H = F_P + F_Q$$

where F_P is the structure factor of the known part and F_Q that of the unknown part, at the same reciprocal lattice point. Thus the intensities recorded will be:

$$F_HF_H{}^* = F_PF_P{}^* + F_QF_Q{}^* + F_PF_Q{}^* + F_P{}^*F_Q$$

The Ramachandran and Raman α-synthesis reconstructs the crystal structure by taking the Fourier transform of $F_P|F_H|^2$, that is:

$$F_P|F_P|^2 + F_P|F_Q|^2 + F_P{}^2F_Q{}^* + |F_P|^2F_Q \qquad (2)$$

which is identical in form to (1). If we consider the non-centrosymmetric case we require the condition that $F_PF_P \neq F_PF_P{}^*$. That is, we must have a non-centric configuration in the part of the structure that is known. A measure of this can be given by the Fourier transform of $F_P{}^2$ (ref. 5). The need for this condition arises from the superposition of the enantiomorphic structures in the crystallographic case. In contrast these two images are separated in holography due to the physical separation of T_P and T_Q in the recording of the hologram. In the centro-symmetric crystal structure the two overlapping images coincide.

A second-order improvement on the α-synthesis is produced by the β-synthesis[4] in which $\frac{|F_H|^2}{F_P{}^*}$ replaces $F_P.|F_H|^2$ as coefficients. While this is easy to achieve in crystallography it may present greater difficulties in optics.

We thank the National Science Foundation and also the National Institutes of Health for supporting part of this work.

ENGINEERING

Hysteresis in the Flow through an Orifice

In a recent investigation into the behaviour of square-edge circular orifices a well-defined hysteresis in the flow was measured. This was obtained with air for a number of orifices of different diameters but of the same length/diameter ratio, equal to one-half. The experimental measurements were made under carefully controlled conditions and could be reproduced at different times.

It is curious that this phenomenon had not been encountered earlier in the long history of investigation of the flow of compressible fluids.

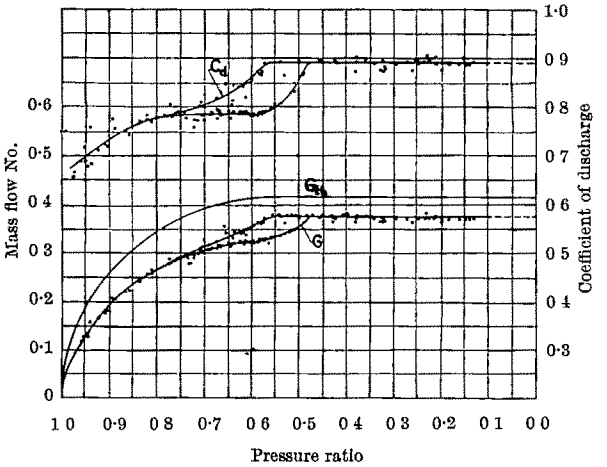

Fig. 1. G, Mass flow number; C_d, coefficient of discharge, G_{th}, theoretical mass flow number based on isentropic flow

The precise nature of the hysteresis is at present under detailed investigation, but it is thought that it is essentially a manifestation of the Coanda effect. It is seen from Fig. 1 that the orifices are choked when, presumably, attachment of the jet is fully secured. The measured mass flows are also the highest among a number of different orifices (thirty-eight in all) with length/diameter ratios ranging from 0·05 to 2·0.

GEOLOGY

Greenstones from the Central Valley of the Mid-Atlantic Ridge

In a preliminary report[1] of a recent study of the morphology of the Mid-Atlantic Ridge about 22° N. latitude, attention was directed to the dredging of a suite of greenstones from the western face of the central valley. Although similar rocks have been recently reported from the Carlsberg Ridge[2] in the Indian Ocean, rocks of this type have not been previously recorded from the Mid-Atlantic Ridge. Preliminary petrographic examination and chemical analysis of the Mid-Atlantic Ridge greenstones justify the present interim report.

The collection from the upper slope (Dredge 2, 2,670–2,050 m) consists, as noted[1], of fragments of greenstone, basalt, and partly metamorphosed basaltic tuff. The fragments exhibit a thin manganiferous coating, usually on all sides. This observation and the angularity of the fragments suggest that they were collected from a slowly accumulating talus slope. The collection from the base of the slope (Dredge 3, 4,000–3,200 m) consists of greenstones, and rare fragments of diabase. The greenstone fragments exhibit only very thin and spotty manganiferous coatings, rarely on more than two faces. The distribution of these coatings, and the fresh uneroded aspect of the uncoated faces, indicate that these rocks had been only recently exposed. The preservation, unbroken, of thin platey fragments in Dredge 2 we take to indicate that the fresh surfaces of the Dredge 3 fragments are unlikely to have been produced by fracturing within the dredge.

The greenstones consist of actinolite, epidote, chlorite and plagioclase in various proportions. The latter is mainly albite although some specimens contain relics of more calcic plagioclase. Dredge 2 contains greenstones which are essentially free of epidote whereas in those in Dredge 3 epidote is abundant. Although searched for specifically, zeolites and pumpellyite have not been noted in the 13 greenstones which have so far been examined in detail.

Most of the greenstones are not deformed. In some of the specimens shear planes occur but they are widely spaced and give no well-defined fabric. Because of this lack of intense penetrative deformation, the pre-metamorphism textures are preserved. These show that some of the greenstone fragments were derived from submarine basaltic flows and others from basaltic tuffs.

One of the greenstones analysed has unusually high sodium content (Table 1, No. 1). This specimen is textur-

† Calculated assuming all sulphur in pyrite, the only sulphide visible in polished sections.

ally characterized by albite veins, dispersed pyrite and rare relict labradorite. These features suggest that the 'spilitic' composition is a result of hydrothermal albitization during metamorphism. Except with regard to their water content, many of the greenstones (for example, Table 1, No. 2) were evidently derived isochemically from basalts.

The greenstones are associated with basalts in Dredge 2 and with rare fragments of diabase in Dredge 3. Table 1 (No. 3) gives an analysis of a fresh basalt from Dredge 2. This basalt consists of microlites of plagioclase and olivine in a glassy matrix containing rare phenocrysts of plagioclase and olivine. Detailed petrographic and chemical data on these basalts and diabases will be included in the final report on the greenstones.

The occurrence of greenstones raises several questions about the nature of the Mid-Atlantic Ridge. These rocks are not hornfelses and cannot be interpreted as the result of contact metamorphism. The mineral assemblages are in the greenschist metamorphic facies, which is often taken to indicate temperatures of 300°–500° C and water pressures between 3 and 8 kbar (ref. 3). Even in the deep sea, such pressures, along with sustained periods of heating, would require that the original basalts and tuffs were buried under a considerable thickness of subsequent flows or sediments. Because there are very few experimental data available on the actual stability ranges of greenschist assemblages, precise estimates of minimum and maximum depths of burial cannot yet be made. Recovery of the rocks by dredging shows no overburden now to be present; its elimination in recent times by other than tectonic processes presents great difficulties. The burial postulated appears to require a halt in, or a temporary reversal of, the upward movement of material underneath a rift zone, as suggested by Hess[4]. The subsequent raising of buried material to the sea floor, and its exposure there, seems to us perfectly consistent with the suggested tectonic patterns.

Matthews *et al.*[2] have attributed origin of chlorite-rich metamorphosed basalts and gabbros recovered from the Carlsberg Ridge to hydrothermal processes resulting from cross-faulting. Such a suggestion is not admissible as explanation of the fresh greenstone occurrences on the Mid-Atlantic Ridge; no cross-faulting is reflected in the bottom topography within almost 30 min north or south of their location.

If greenstones similar to those from 22° N. prove to be quantitatively important constituents of parts of the Mid-Atlantic Ridge, interpretations of seismic, magnetic and gravity data from the Ridge cannot be based on models which assume the presence only of fresh basaltic rocks, serpentine and unserpentinized ultramafics in a simple layer-cake sequence. The probability that greenstones are of general importance in the structure of the Ridge is increased by our finding of greenstone fragments in the coarse fraction of sediments from the western flank (P.C. 22, South Pond)[1]: in the specimens examined, chlorite is often associated with phillipsite. Careful examination of all undescribed materials from the Mid-Atlantic Ridge is important in assessing the true abundance of greenstones. Because of the fine-grained nature of the rocks from 22° N., only petrographic inspection of thin sections or of grains, combined with X-ray diffractometry, has allowed precise identifications.

Additional petrographic examinations and chemical analyses are now in process, and an extended report of the study will be published elsewhere. We thank Peter L. Sachs and the scientific party and crew of R.V. *Chain* for their part in the dredging, and Eugene Jarosewich for making the chemical analyses. Isotopic Ages of Minerals from the Pre-Cambrian Complex of the Malverns

THE Malvern Hills, Worcestershire, form one of many Pre-Cambrian inliers of the Welsh Borderland[1]; rocks of Pre-Cambrian age are divided into Malvernian 'schists and gneisses' and the overlying Warren House volcanic group. The analyses reported in the following communication are from minerals occurring within the supposed metamorphic rocks and do not include any from the volcanic group, no suitable material having been obtained from the latter. The 'schists and gneisses' were identified as Malvernian more than a century ago[2], but the origin of their structures remained a puzzle, and it was a matter of some controversy as to whether the rocks were igneous or metamorphic[3,4]. However, most of the rocks seen by us are igneous, usually hydrothermally altered and sheared, but still retaining igneous textures and occasionally igneous mineralogy. Such schistose rocks as have been observed are either in shear zones or in fault blocks, and true gneisses, in the usual sense of high-grade, banded, metamorphic rocks, are absent. The commonest rocks are of intermediate igneous type, classifiable as mafic diorite or tonalite. Amphibolites of various kinds, usually with igneous textures, are another common rock type. Ultramafic rocks are usually rich in tremolite or actinolite, with biotite or chlorite. Granitic rocks are rare, but syenitic veins and pegmatites frequently occur. The usual mineral assemblages are those of the greenschist or epidote–amphibolite metamorphic facies. It is generally agreed that the alteration of the igneous rocks of the Malvernian occurred in the Pre-Cambrian, as no equivalent hydrothermal or metamorphic activity has affected the Cambrian or later strata.

The Pre-Cambrian of the Malverns occurs along a major north–south structural line, regarded as of Late-Carboniferous age[5,6], but which must have been initiated earlier. To the east is Trias, and Cambrian and Silurian lie to the west. The eastern junction is most probably a fault[6], as is much of the western boundary. Groom[5] believed that the entire western boundary was faulted, but recent exposures support Holl's[2] view that both the Cambrian and the Lower Silurian (Upper Llandovery)[7–10] rest unconformably on the Malvernian. There is also discordance between the Cambrian and the Silurian. The conclusion that the Upper Llandovery rests unconformably on the Malvernian, based on the exposure in the Gullet Quarry, and at the Sycamore Tree exposure, has been disputed[11], but having seen the field evidence at the Gullet we strongly support the interpretation of unconformity as stated by Reading and Poole[7]. There were, therefore, three distinct phases of vertical movement, one

Pre-Cambrian, one Post-Cambrian and Pre-Upper Llandoverian, and one Late Carboniferous. A further event in the area is the intrusion of a set of basic sills and stocks into the Cambrian, but not into the Silurian or later strata[12,13]. Whether or not any representatives of these cut the exposed Pre-Cambrian does not appear to be known, but no Pre-Cambrian Malvernian rock in our possession conforms to the descriptions available of the Post-Cambrian intrusions, nor were any unsheared intrusions seen in the Pre-Cambrian in the field.

Our results suggest that it would be of interest to identify the precise stratigraphic position of the Cambrian of the area, in particular that which rests on the Malvernian. An *Olenellus* fauna, indicating a Lower Cambrian age, is known from the Welsh borderland[1], but the Malvern Cambrian has never yielded Lower Cambrian tribolites. It is thought, however, to be Lower Cambrian in its lithological similarity to the proved Lower Cambrian of Comley, Shropshire, its position below the Middle Cambrian, and a fauna of horny brachiopods and *Hyolithus*[14]. As it is the supposed Lower Cambrian which is known to rest on the Malvernian, there would appear to be a good case for further palaeontological investigation into these rocks, in the light of the age data reported and their possible significance for the geological time scale.

The investigation of mineral ages in the Malverns is restricted by the choice of material; perfectly fresh minerals are all but absent (Table 1). The whole rocks so far available to us have such low rubidium–strontium ratios that it was not thought worthwhile to analyse them at this stage of the investigation. Analyses were made for potassium–argon ratio at Oxford by D. Rex, for potassium–argon ratio at Edmonton by R. St. J. Lambert (under the instruction of H. Baadsgaard) and for rubidium–strontium ratio at Oxford by R. St. J. Lambert. Standard techniques were used throughout; the decay constants used are given at the foot of the tables. The potassium–argon ratios, Table 2, and the rubidium–strontium ratios, Table 3, show a concentration of apparent ages at or closely approaching 600 m.y., with a tail of lower ages. Agreement between laboratories, and between potassium–argon ratios on two biotites, one hornblende and one muscovite and rubidium–strontium ratios on one biotite, all at 590 ± 20, suggests that some definite event must have occurred in the history of the Malverns at that time or slightly earlier. The discordant results are perplexing; no obvious explanation is known for the difference between the rubidium–strontium and potassium–argon age of biotite 21038, unless the very subsidiary chloritization (about 5 per cent) of this biotite has occurred late and affected only the rubidium–strontium daughter–parent ratio. The discrepancy between 21038 biotite and hornblende may have a petrographic explanation; the hornblende is sieved with calcite, apparently replacive and associated with late veins of calcite. The other low age, 510 m.y. on 21045 hornblende, is also from a mineral which has suffered alteration, the hornblende being partly replaced by epidote and chlorite.

The concentration of results near 600 m.y. and the agreement of one rubidium–strontium and the potassium–argon results (the rubidium–strontium ages are not sensitive to choice of reasonable initial $^{87}Sr/^{86}Sr$ ratio in mafic igneous minerals with these high rubidium–strontium ratios) suggest that the last major isotopic event in the Malvernian occurred 590 ± 20 m.y. ago, and was associated with the Pre-Cambrian uplift of these rocks. Whether it is a true rock-forming age cannot definitely be stated (590 m.y. is only a minimum for the true age of these rocks), but even if not, it still remains likely that the event recorded is Pre-Cambrian. It is therefore of possible importance in defining the age of the base of the Cambrian, which is only poorly known[15].

The meaning of the lower apparent ages of from 545 to 485 m.y. is less clear. The lowering of the 600 m.y. ages could have been accomplished during the period of Ordovician igneous activity or during the Pre-Upper Llandoverian earth movements, or during the Late Carboniferous movements. The results so far seem to indicate that either of the first two possibilities is more likely than the last.

This work forms part of the age and isotope investigations being carried out in the University of Oxford; we thank S. Moorbath, H. G. Reading and N. J. Snelling for discussions.

Table 1. Specimen Localities and Descriptions

21038 Grid Ref. 770441. Lower Toll Gate. Mafic hornblende–biotite syenite (pegmatitic). Hornblende very pale green prisms up to 1 cm, containing about 20 per cent calcite; biotite, 1 cm, fresh but deformed, with angular kinks in cleavage flakes, minor marginal chloritization; plagioclase almost completely sericitized and epidotized; microcline fresh; accessory apatite, sphene and hematite.

21039 (As 21038). Ultramafic rock consisting of 30 per cent biotite, pale brown and deformed as in 21038; 65 per cent amphibole, about half pale-green hornblende ('actinolite') and about half colourless cummingtonite. Accessory primary colourless chlorite, oxide and calcite.

21045 Grid Ref. 771496. Clock tower, North Hill Quarry. Hornblende diorite: medium-grained hornblende (50 per cent of rock) mostly fresh, set in turbid plagioclase, strongly epidotized. Hornblende locally altered to epidote plus chlorite.

20633 Grid Ref. 768477. East face of Brewery Quarry, Upper Wyche. Amphibolite, medium-grained, rich in fresh green hornblende, with minor turbid plagioclase. Epidote on joint planes; cut by thin feldspar-quartz veins.

20634 (As 20633). Muscovite–quartz–potassium–feldspar vein cutting 20633-type rock. Muscovite (up to 2 mm) set in a turbid potassium-feldspar and quartz matrix.

Structure and Evolution of the Volcanic Cauldrons, Ring Complexes and Associated Granites of the Georgetown Inlier, Queensland

The Georgetown Inlier in North Queensland covers an area of about 37,000 square miles and lies on the western flank of the Palaeozoic Tasman Geosynclinal Zone

(Fig. 1). It consists largely of Pre-Cambrian metamorphic and granitic rocks, and a suite of Upper Palaeozoic acid igneous rocks. The Upper Palaeozoic acid igneous rocks, which occupy an area of about 10,000 square miles, include extensive acid volcanics and associated granitic intrusions, and form a well-defined petrographic province[1]. The volcanic rocks consist predominantly of rhyodacite[2] welded tuff[3] with subordinate rhyolite, trachyandesite, andesite and basalt, belonging to the calc-alkaline rock series. The intrusive rocks are mainly adamellite[2] with subordinate granite and granodiorite.

About 1,000 cubic miles of rhyodacite welded tuff has been preserved in eleven cauldron subsidence areas ranging from 8 to 75 miles long. Six ring complexes occur in association with the cauldrons; five contain both volcanic and intrusive rocks, and the sixth is entirely intrusive. The position of the volcanic cauldrons and the ring complexes appears to have been controlled by pre-existing fractures in the Pre-Cambrian basement. Stocks of medium-grained adamellite which intruded the volcanics in the cauldrons and ring complexes crystallized under a hood of welded tuff sheets only 500–2,000 ft. thick.

In the cauldrons the initial event was the eruption of viscous acid magma from vents aligned along the peripheral faults, accompanied in some cauldrons by lacustrine sedimentation nearby. As the fluidity of the magma increased, vesicular rhyodacite flows and air-fall tuff and breccia were erupted. Interbedded with and overlying these units are thin welded tuff sheets in simple cooling units[3] generally less than 100 ft. thick. The final volcanic event was the eruption of fluidized rhyodacite magma from the peripheral fissures and ring fractures to form voluminous welded tuff sheets in compound cooling units[3] up to 1,500 ft. thick, which filled the cauldrons. Finally, high-level granite stocks were emplaced by underground cauldron subsidence in the base of the downfaulted volcanics.

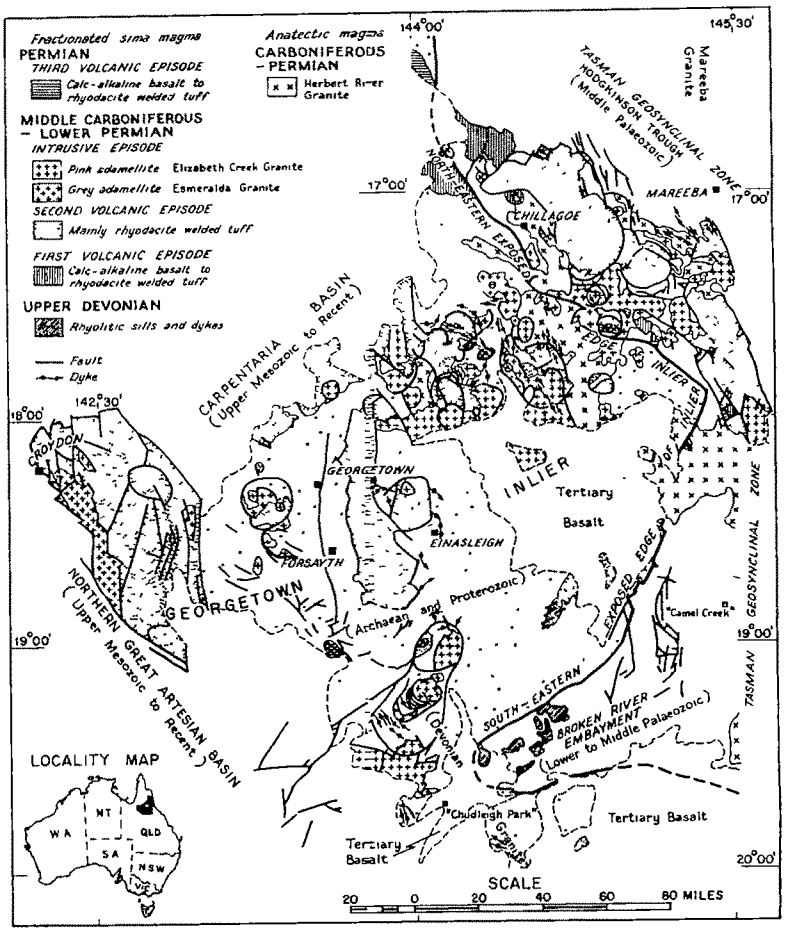

Fig. 1. Major structural and petrological elements of the Upper Palaeozoic Acid Igneous Province, North Queensland

The sequence of events in the ring complexes is similar to that in the cauldrons, and may be grouped into three phases. However, whereas the magma for the volcanic events in the cauldrons was derived from the main, deep-seated magma chamber, the magma for the volcanic phases (1 and 2) in the ring complexes was derived mainly from magma differentiated in a high-level magma chamber formed by underground cauldron subsidence and isolated above the main magma chamber. About the time phase 3 began, the high-level chamber was flushed by magma rising from the main magma chamber, creating a hiatus in the chemical evolution of the complex, and later ring dykes and stocks were derived from this magma.

The structural phases in the ring complexes were: (1) Early volcanic phase, with eruption of acid volcanics from small central vents. (2) Caldera phase, with eruption of andesitic to rhyolitic air-fall pyroclastics and moderately large ash flows from ring dykes filled with fluidized acid magma. (3) Underground cauldron subsidence phase, with the intrusion of ring dykes and stocks.

The formation of acid magma for the comagmatic granites and pyroclastic flows is believed to be an integral phase of geosynclinal development. During the orogenic phase of development of the Palaeozoic geosyncline adjacent to the Pre-Cambrian inlier, acid magma was fractionated from basic rocks in the lower crust under the inlier. The determination of a mantle-strontium ratio ($^{87}Sr/^{86}Sr = 0{\cdot}701$, W. Compston, personal communication) for a rhyodacite welded tuff corroborates this hypothesis. According to radiometric age data, the acid magma accumulated for about 50 million years, but remained *in situ* until the start of the post-orogenic phase, when it was intruded over a period of 30 million years or less. The production of acid magma domed the crust, placing it in a state of tension. Magma rose along pre-existing major faults and, on reaching the surface, caused a drop of pressure in the magma chamber. This allowed the accumulation of a volatile-rich phase which was erupted to the surface as pyroclastic flows. Where the magma was most depleted, subsidence of crustal blocks initiated cauldron subsidence. This was followed by crustal instability and the magma rose by high-level major block stoping. At various stages the volatile-rich part was erupted to produce further pyroclastic flows at the surface. Finally, the magma intruded the pyroclastic flow sheets and crystallized as an adamellite.

A contemporaneous granite crops out along the north-eastern margin of the Georgetown Inlier and within the adjacent Palaeozoic geosyncline, the magma for which is thought to have formed by anatexis at the base of the Palaeozoic geosyncline, in the manner outlined by Tuttle and Bowen[4] and Walton[5].

CRYSTALLOGRAPHY

Thermal Expansion of Rubidium Dihydrogen Phosphate

A PROGRAMME of investigation into the temperature variation of the lattice parameters of tetragonal crystals, isomorphous with potassium dihydrogen phosphate, in the high-temperature region, has been undertaken in this laboratory. Results on potassium dihydrogen phosphate[1], ammonium dihydrogen phosphate[2] and potassium dihydrogen arsenate[3] have already been published. This communication presents the results of the precision determination of the unit cell dimensions of rubidium dihydrogen phosphate at different temperatures between 29° C and 78° C and also the principal coefficients of its thermal expansion obtained from these data.

Crystals of rubidium dihydrogen phosphate were prepared by slow evaporation of an aqueous solution of rubidium carbonate neutralized with an aqueous solution of hypophosphoric acid. X-ray powder pictures were taken with a high-temperature, back-reflexion camera[4] using copper K_α radiation. Six unambiguously indexed $K_{\alpha_1\alpha_2}$ doublets, with their sine^2 θ values greater than 0·866, were employed in calculating the values of the a and c parameters, using the conventional least-squares technique. An error analysis made for a film taken at 35° C, by the method given by Jette and Foote[5], gave the standard errors in the values of a and c as 0·013 per cent and 0·019 per cent, respectively. Standard errors in the values of the parameters at other temperatures were assumed to be of the same order.

Table 1 gives the values of the two parameters at different temperatures, and the following expressions were obtained for their temperature dependence by the usual statistical methods.

$$a_t = 7{\cdot}6054 + 21{\cdot}11 \times 10^{-5}\,(t\text{-}20)$$
$$c_t = 7{\cdot}2989 + 37{\cdot}95 \times 10^{-5}\,(t\text{-}20)$$

Here a_t and c_t are the values of the two parameters in Ångstroms at t° C. Slight extrapolation of the present data gives the values of the parameters at 20° C as $a = 7{\cdot}6054$ Å and $c = 7{\cdot}2989$ Å and these are found to be in good agreement with the values reported by Magyar[6].

Table 1. VALUES OF THE LATTICE PARAMETERS OF RUBIDIUM DIHYDROGEN PHOSPHATE AT DIFFERENT TEMPERATURES

t° C	a (Å)	c (Å)
29 0	7 6078 ± 0 0009	7 3026 ± 0·0014
35 0	7 6080	7·3040
50 0	7·6114	7 3109
61·5	7·6150	7 3139
74·0	7 6168	7·3196
78 0	7 6174	7·3209

Within the accuracy of the measurements, both the parameters show a linear increase with temperature. The principal coefficients of thermal expansion, defined by the relation $\alpha = 1/L_{20}(dL/dt).(L = a \text{ or } c)$, come out as $\alpha_a = 27{\cdot}75 \times 10^{-6}$/°C and $\alpha_c = 52{\cdot}0 \times 10^{-6}$/°C. It is interesting to note that, like potassium dihydrogen phosphate and potassium dihydrogen arsenate, the coefficient of expansion of rubidium dihydrogen phosphate along the tetragonal axis is greater than that in any direction in a perpendicular plane. This feature is being discussed separately in terms of the structures of these crystals.

One of us (A. A. K.) thanks C.S.I.R. (India) for the award of a research fellowship.

CHEMISTRY

Contact Angles of Mercury on Low-energy Solids

THE recent theory of Fowkes[1-5] concerning the attractive forces at interfaces leads to the following relationship between cosine of contact angle (θ) and liquid surface tension (γ_L):

$$\cos\theta = -1 + 2\sqrt{\gamma_S{}^d}\left(\frac{\sqrt{\gamma_L{}^d}}{\gamma_L}\right) \qquad (1)$$

where $\gamma_S{}^d$, $\gamma_L{}^d$ are the dispersion force contributions to the solid surface tension and liquid surface tension respectively.

A plot of $\cos\theta$ against $\sqrt{\gamma_L{}^d}/\gamma_L$ for the data of Zisman[6,7] for four low-energy surfaces gives good agreement with equation (1). The range of surface tensions investigated was, however, not great. The only liquid investigated with a surface tension greater than water (γ_L = 72 dynes/cm) was mercury (γ_L = 485 dynes/cm), for which values were published only for the following surfaces: polytetrafluoroethylene, 150° (ref. 8); octadecylamine monolayer on platinum, 146° (ref. 9); perfluorodecanoic acid monolayer on platinum, 152° (ref. 10).

Fowkes[5] quotes a value for paraffin wax $\cos\theta = -0{\cdot}9$ (θ = 154°). These points do not fall on Fowkes's plot of $\cos\theta$ against $\sqrt{\gamma_L{}^d}/\gamma_L$. Fowkes[5] comments: "It is possible that some wax spread on mercury resulting in a decrease of surface tension and therefore too high a contact angle".

Few measurements of contact angle of mercury on low-energy solids seem to have been made, and those made by Zisman consisted only of the mean of three measurements with no record of the scatter. The measurements in this communication are put forward in an attempt to increase the available facts.

Fowkes's theory might be expected to be particularly accurate for mercury on low-energy solids and the results should provide a sensitive confirmation of the validity of his theory.

Measurements have been made, therefore, of the contact angle of mercury on polytetrafluoroethylene, paraffin wax, and polyethylene.

Clean mercury was prepared according to the recommendation of Nicholas *et al.*[11]. It was distilled, washed successively with dilute nitric acid and caustic soda solution, distilled again and then shaken, successively, with 50 per cent nitric acid, distilled water, acetone, ether and filter paper before being applied as small drops to the test surface by a clean hypodermic syringe with a polytetrafluoroethylene base. Measurements were made as rapidly as possible—usually within 1 min of application.

Paraffin and polyethylene surfaces were prepared by the methods of Fox and Zisman[12], freshly cut surfaces being melted against cleaned glass slides, which were removed immediately before use. Clean, flat surfaces of polytetrafluoroethylene were prepared by fine polishing on successive grades of powdered emery, final traces of abrasive being removed by lens tissues. Contact angle measurements were made using a horizontal microscope technique as described elsewhere[13]. The surfaces were mounted on the rotating stage when in a vertical plane and the advancing and receding angles obtained by rotating the stage until movement just ceased. A goniometer eyepiece was used to measure angles.

Results are given in Table 1. They include the 95 per cent confidence limits and the standard deviation on $\cos\theta$.

It will be noted that the values for polytetrafluoroethylene (151·7° advancing, 150·2° receding) are very close to the value of 152° reported by Fox and Zisman[8]. The values for paraffin wax, on the other hand (141·1° advancing, 140·9° receding), do not agree with the 154° reported by Fowkes[5].

Table 1. CONTACT ANGLES OF MERCURY ON LOW-ENERGY SURFACES

Surface	Advancing angle					Receding angle				
	No. of observations	θ (degrees)	Mean cos θ	95% confidence limit	Standard deviation	No. of observations	θ (degrees)	Mean cos θ	95% confidence limit	Standard deviation
Paraffin wax	31	141·1	−0·7793	0·0067	0·0188	37	140 9	−0·7765	0·0048	0 0145
Polyethylene	8	148·0	−0·8477	0·0064	0·0076	7	145·5	−0·8231	0 0177	0 0191
Polytetrafluoroethylene	17	151·7	−0·8805	0·0092	0 0187	16	150·2	−0·8678	0·0171	0 0333

It must be admitted that mercury in laboratory air does not retain the surface tension value of 485 dynes/cm assumed by Fox and Zisman[8]. Nicholas *et al.*[11] found 400–380 dynes/cm to be typical.

However, using the foregoing contact angle data one can substitute in equation (1), using Fowkes's values[5] for γ_S^d and γ_L^d, to find the surface tension value for mercury which would satisfy that equation.

Using my mean values for contact angles, the results are as follows:

Polyethylene	γ_L = 1,073 dynes/cm
Paraffin wax	γ_L = 641 dynes/cm
Polytetrafluoroethylene	γ_L = 1,071 dynes/cm

The discrepancy from Fowkes's theory cannot therefore be explained by contamination of the mercury since it is necessary to postulate an increase of surface tension rather than a decrease to comply with his equation.

Primary Process in the Photolysis of Alkyl Iodides

RECENTLY, Kasper and Pimental[1] have detected stimulated emission from the transition $I(5p^2P_{1/2}) \rightarrow I(5p^2P_{3/2}) + h\nu$ (1·315μ) resulting from the flash photodissociation of methyl and trifluoromethyl iodides. This provided the first direct observation of electronically excited iodine atoms produced from the photolysis of alkyl iodides. A spectral analysis of methyl iodide by Porret and Goodeve[2] had previously indicated that $I(5^2P_{1/2})$ should be predominantly produced on the photolysis of this compound. Furthermore, these authors pointed out the close similarity between the spectra of the lower aliphatic iodides. The work described in this communication, which utilized kinetic spectroscopy in the vacuum ultra-violet region of the spectrum, confirms the work of Kasper and Pimental and extends the observations to ethyl, propyl and butyl iodides. Preliminary observations on the photolysis of hydrogen iodide are also reported here.

We have previously observed both excited ($5^2P_{1/2}$) and ground state ($5^2P_{3/2}$) iodine atoms in absorption resulting from the flash photolysis of molecular iodine in the presence of excess argon[3]. This technique has also been used to monitor the large concentration of excited atoms that accompanied the population inversion on the photolysis of CF_3I, and the relatively long life-time of the excited atoms in this system allowed deactivation by various added gases to be investigated[4].

The spectrum of CF_3I ($P_{CF_3I} < 5$ mm) does not interfere with the strong atomic transitions at 1783 and 1799 Å most convenient for plate photometry. The molecular spectra of the other unsubstituted alkyl iodides investigated, on the other hand, obscured the region below 2000 Å and, for this reason, conditions were sought which allowed the detection of the weaker transition of the excited atom at 2062 Å. The use of high concentrations of CF_3I ($P_{CF_3I} > 5$ mm; $P_{Ar} = 50$ mm; $E = 1{,}024$ Joules) revealed not only the transition at this wave-length but even weaker transitions at 1876 and 1844 Å (Fig. 1). Table 1 lists those transitions that have now been observed in absorption for atomic iodine.

Table 1

λ (Å)	Transition
1783	$6s(^2P_{3/2}) \leftarrow 5p(^2P_{3/2})$
1799	$6s(^2P_{1/2}) \leftarrow 5p(^2P_{1/2})$
1830	$6s(^4P_{5/2}) \leftarrow 5p(^2P_{3/2})$
1844	$6s(^4P_{3/2}) \leftarrow 5p(^2P_{1/2})$
1876	$6s(^4P_{1/2}) \leftarrow 5p(^2P_{1/2})$
2062	$6s(^2P_{3/2}) \leftarrow 5p(^2P_{1/2})$

The transition at 2062 Å could be detected on photolysing ethyl, propyl and butyl iodides but in the case of methyl iodide this is overlain by a strong band in the molecular spectrum[5]. It was found possible by carefully reducing the concentration of CH_3I ($P_{CH_3I} = 0{\cdot}025$ mm; $P_{Ar} = 50$ mm; $E = 1{,}024$ J) to observe the sharp atomic lines at 1799 and 1783 Å at short delay (13·8 μsec) through the relatively diffuse molecular spectrum and that the intensities of these transitions indicated a population inversion. The photolysis of methyl iodide has been studied by time-resolved mass-spectrometry[6], and the rapid production of molecular iodine has been accounted for in terms of the proposed reaction:

$$I(5^2P_{1/2}) + CH_3I \rightarrow I_2 + CH_3 \quad \triangle H = -5{\cdot}2 \text{ kcal}$$

We consider the analogous reaction with CF_3I, where molecular iodine is only observed at long delay, to make a negligible contribution to the decay of the excited iodine atoms[4]. A strong spectrum of the methyl radical was also observed during the first 100 μsec after the flash ($P_{CH_3I} = 0{\cdot}5$ mm; $P_{Ar} = 50$ mm; $E = 1{,}024$ J) previously observed in this system by Herzberg[7].

The decay of $I(5^2P_{1/2})$ resulting from the photolysis of ethyl iodide could be studied by monitoring the transition at 2062 Å by plate photometry using a Joyce–Loebel double-beam microdensitometer (Mark III). The decay roughly exhibits first-order kinetics with respect to both excited atoms and the concentration of ethyl iodide

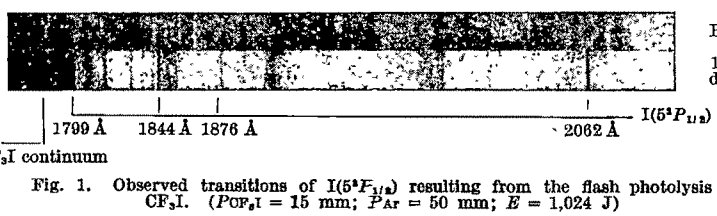

Fig. 1. Observed transitions of $I(5^2P_{1/2})$ resulting from the flash photolysis CF_3I. ($P_{CF_3I} = 15$ mm; $P_{Ar} = 50$ mm; $E = 1{,}024$ J)

itself (Fig. 2). Deactivation by argon is insignificant[3,4]. By comparison with previous experiments on CF_3I, we estimate that about 40–50 per cent of ethyl iodide is photolysed in each case. This allows us to estimate a second-order decay constant for the removal of $I(5^2P_{1/2})$ by EtI from the two slopes in Fig. 2. This yields a value for the rate constant given by $k = 2{\cdot}2 \pm 0{\cdot}4 \times 10^8$ l. m^{-1} sec^{-1}. The only data on spin-orbit relaxation of excited iodine atoms with which we can compare this result is the decay constant for propane ($k = 3{\cdot}5 \times 10^7$ l. m^{-1} sec^{-1}) (ref. 4). The decay of $I(5^2P_{1/2})$ in this system could also, however, be due to deactivation or reaction with the products of the photolysis of ethyl iodide[8] or a chemical reaction with EtI itself, analogous to that already discussed here for methyl iodide. More detailed work would be necessary to resolve this point. HI was not detected in these experiments and we are therefore unable to support the mechanism hitherto suggested[8] in which this molecule is a primary product of photolysis.

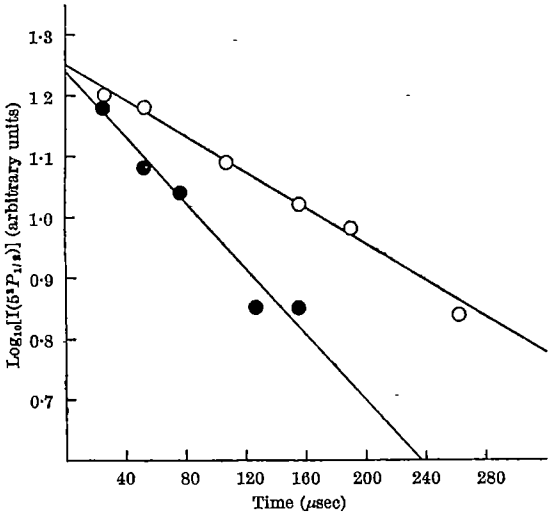

Fig. 2. Decay of electronically excited iodine atoms ($5^2P_{1/2}$). $\log_{10}[I(5^2P_{1/2})]$ (arbitrary units) versus time (μsec). ○, P_{EtI} = 0·5 mm; P_{Ar} = 100 mm; E = 1,024 J. ●, P_{EtI} = 1 mm; P_{Ar} = 100 mm; E = 1,024 J

The 2062 Å transition was observed at short delay on the photolysis of both propyl iodine (P_{PrI} = 0·5 mm; P_{Ar} = 50 mm; E = 1,024 J) and n-butyl iodide (P_{BuI} = 2·0 mm; P_{Ar} = 50 mm; E = 1,024 J). No attempt was made to monitor the decay of the excited atoms as the spectral intensity was weak, that in butyl iodide being weakest. Our observations on the compounds considered are consistent with the general primary process:

$$RI + h\nu \rightarrow R + I(5^2P_{1/2})$$

where $R = CF_3$, CH_3, C_2H_5, C_3H_7 and n-C_4H_9

The growth and decay of the relatively low concentration of $I(5^2P_{1/2})$ that we have observed in the photolysis of HI and DI indicate that the iodine atoms are produced predominantly in the ground state on photolysis. Our experiments further indicate that the yield of excited atoms compared with ground state atoms, resulting from the reaction:

$$H + HI \rightarrow H_2 + I(5^2P_{1/2})$$

is low. The emission from the excited iodine atoms produced from the foregoing reaction has been observed in flow-discharge experiments by Polanyi *et al.*[9].

We thank Prof. R. G. W. Norrish for his encouragement throughout the course of this work and for laboratory facilities. One of us (R. J. D.) thanks the Department of Scientific and Industrial Research for a maintenance grant during the tenure of which this work was carried out.

BIOPHYSICS

Some Flow Properties of Whole Blood

The purpose of this communication is to outline some observations that have been made on the flow of whole blood when the material has been contained between parallel plates in relative rotation. The top plate was 7·5 cm diameter, while the bottom plate was of the 'reservoir' type to obviate the possibility of the material drying out at the periphery of the (narrow) gap.

The main results obtained were:

(1) If an oscillatory motion was superimposed on steady shearing the maximum torque on the top plate during the combined motion was scarcely more than the torque in steady shearing alone; the minimum was considerably less. The average torque was much less in the combined motion and it is possible that the average rate at which work was absorbed was less in the combined motion than in the steady shearing alone. (A later analysis has shown an increase in these two cases.)

(2) The response of the material to oscillatory motion was non-linear below about 20 c/s in these experiments. For a shear rate of the form:

$$s = s_0 \cos \omega t \qquad (1)$$

The stress was of the form:

$$\tau = \sum_{n=1} A_{2n-1} \cos([2n - 1]\omega t - \varphi_{2n-1}) \qquad (2)$$

it comprised a fundamental and odd harmonics. The phase angles φ_{2n-1} may be due to elasticity or time-dependency of the viscosity or yield criterion[2].

(3) A finite lag occurred after the commencement of steady shearing before the main build up of stress, suggesting that geometric hindrance of suspended particles is important.

(4) After cessation of steady shearing a finite time was required for the torque to decay to its terminal value, which may be due to elasticity or re-orientation of the particles.

(5) In steady forward motion the torque built up to a maximum and then decayed. If the motion was reversed, the torque built up much more slowly and to a higher value than in the forward direction.

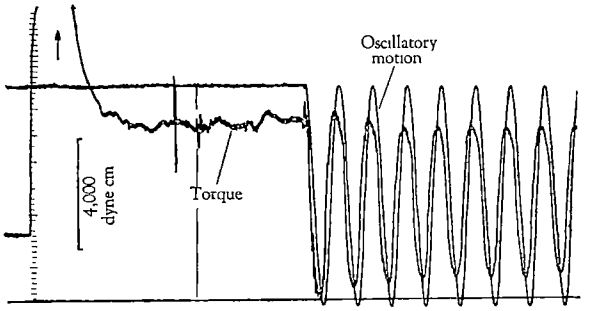

Fig. 1. Steady shearing with subsequent superposition of oscillatory motion. Steady shearing, 18·45 sec^{-1} (periphery), oscillatory strain amplitude 47 (periphery). Frequency, 0·792 c/s gap, 0 001 in. (2×10^{-5} in.)

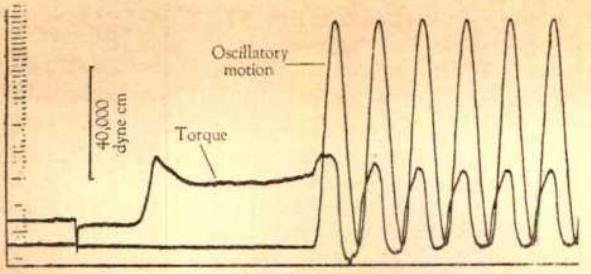

Fig. 2. Steady shearing with subsequent superposition of oscillatory motion. Steady shearing, 12·3 sec^{-1} (periphery), oscillatory strain amplitude 22·8 (periphery), frequency, 2·5 c/s gap, 0·0015 in. (2×10^{-3} in.)

(6) In oscillatory motion alone the torque amplitude would usually decay in time while maintaining a constant strain amplitude.

I have observed all these phenomena in the flow of clay-water systems. Separate complete reports on the clay and blood experiments will be published elsewhere.

Finally it is mentioned that the equation due to Casson[1] which has been applied to blood flow is unsuitable for non-steady flow and would certainly not describe the foregoing phenomena, neither would the well-known power-law which is likewise unsuitable for non-steady flow.

Dental Caries and Enamel Structure

A GENERALLY accepted feature of the histology of ground sections of carious lesions in human dental enamel is the so called 'dark zone'. This zone, which lies at the border of the lesion, between the main body and the translucent zone or normal enamel, shows positive birefringence when the section is placed in quinoline and viewed by polarized light. It has been demonstrated that the positive birefringence in this zone is related to the presence of small inter-crystallite spaces which are inaccessible to media of large molecular size and contain air or vapour which is of low refractive index. This results in positive form birefringence which reverses the negative intrinsic birefringence of the enamel structure[1].

During examination of multiple sections of carious lesions it has been found that this positively birefringent zone is not always present along the advancing front of the lesion. This zone is usually present in the outer third of the enamel in peripheral sections of advanced lesions but sections cut close to the centre of such lesions frequently show absence of this positive zone, particularly in the inner two-thirds of the enamel. However, in some lesions involving only the outer third of the enamel the positive zone is missing along the deepest part of the advancing front. The positive zone is also more marked on the cervical aspect of a lesion than along its occlusal border and lesions involving the cervical enamel are usually found to have a well-marked positive zone surrounding the lesion.

Contour maps, based on isotropic lines in media of differing refractive indices, serve to provide information about the approximate distribution of spaces throughout the lesion[2]. The relationship of the contours in such maps, from a survey of thirty sections of carious lesions, suggests that the speed of advance and severity of attack relative to the structural front involved determine whether the positive zone is broad, narrow or absent. From experiments with artificial caries *in vitro* it seems that the positive zone is more likely to form under slow than rapid attack. As noted, it is in the central and deepest parts of the lesion, where attack may be expected to be most rapid, that the positive zone is frequently absent.

b

Fig. 1. *a*, Ground section of human permanent enamel showing a carious lesion, mounted in quinoline and viewed by polarized light with quartz sensitive tint. The advancing front of the lesion (*A*) shows little evidence of the positively birefringent 'dark zone'. The body of the lesion (*B*) and the surrounding enamel (*C*) show varying degrees of negative birefringence. *b*, Contour map, relating to the section in *a*, based on isotropic lines seen in air and watery media of refractive indices 1·33, 1·41, and 1·47. The approximate percentage of spaces corresponding to the contours is, respectively, 1, 5, 10 and 25 per cent, as indicated. The contours are well spaced-out towards the advancing front, unlike the variable pattern found when the positive zone is clearly marked

In one group of lesions, mostly in first permanent molars, the positive zone was noticeably absent (Fig. 1*a*) and in maps of such lesions the contours showing space distribution, and thus approximate degree of demineralization, were well spread out throughout the lesion (Fig. 1*b*). This is in contrast to the situation more commonly found where the spacing of the contours varies in direct relation to the width of the positive zone. It was found in these lesions that much of the enamel structure appeared to be defective, showing a marked positive birefringence when viewed in air by polarized light. These appearances could not be attributed wholly to variations in prism orientation. It is possible that the well-spaced contours may indicate a slow diffusion of the carious attack into the enamel, but the absence of the positive zone in quinoline suggests that the attack may have moved rapidly through the defective structure. Such circumstances could account for the deep penetrating lesion which suddenly cavitates without warning.

The first permanent molar in which this type of lesion was found undergoes formation both before and after birth. The deciduous dentition formed under similar circumstances is, therefore, of considerable interest. Such reports as exist in the literature concerning caries of the deciduous dentition make no observations which suggest that it is in any way different to that found in the permanent dentition. It is mostly the early approximal lesion that has been the subject of investigation. However, in an examination of gross caries in 67 teeth of children under the age of four, a group increasingly affected with the

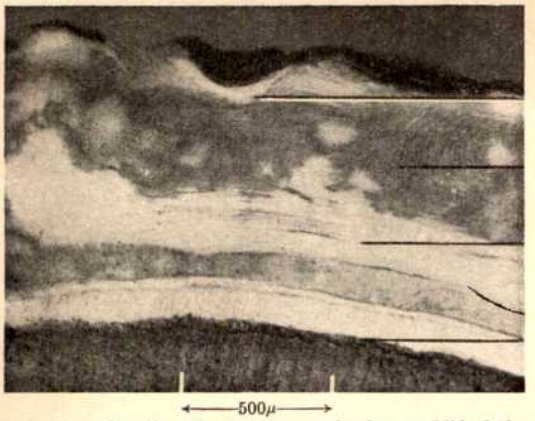

Fig. 2. Ground section of a deciduous molar from a child of 2½ years. The section is mounted in quinoline and viewed by polarized light with quartz sensitive tint. The enamel surface shows irregular pitting and there are prismless 'banded' areas which are negatively birefringent (*A*) in the enamel, interspersed with areas of positively birefringent prismatic structure (*B*); the enamel-dentine junction is shown at (*C*)

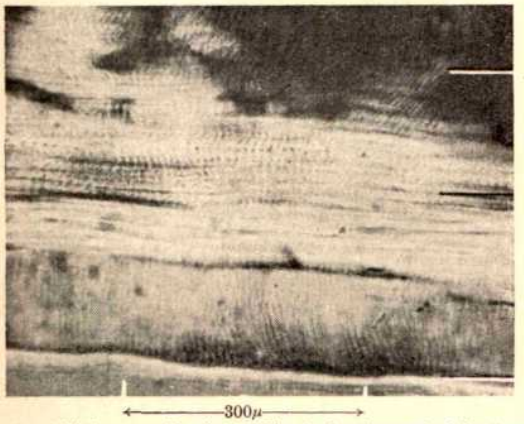

Fig. 3. A higher magnification of Fig. 2, showing part of the 'banded' area (*A*), positively birefringent area (*B*), and enamel-dentine junction (*C*)

ravages of dental caries, several forms of defect in the enamel structure have been noted: (1) Marked positive birefringence of the inner two-thirds of enamel, similar to that seen in the permanent enamel, was present in some of the teeth. Where this occurred the area involved was positively birefringent not only in air but also in water, indicating in all probability 5 per cent or more spaces in the structure. (2) A total lack of prism structure in parts of the enamel, with or without a hypoplastic enamel surface, was present in many of the teeth examined. The regions involved showed an appearance akin to fibrous banding which was highly negatively birefringent with areas of positively birefringent enamel interspersed throughout the structure (Figs. 2 and 3).

These appearances could be found in all the deciduous teeth examined: (*a*) in the prenatal enamel alone; (*b*) in the postnatal and particularly the outer enamel; (*c*) in both prenatal and postnatal enamel.

It would seem that the rapid spread of dental caries may be related to defects which are present in the enamel structure and which facilitate progress of the lesion.

In an attempt to determine whether a common factor exists, such as drug therapy or nutritional deficiency in pregnancy and infancy, which might account for the structural defects in the enamel, the mothers of the affected children and their medical practitioners are being approached for the relevant history.

BIOCHEMISTRY

Investigations of the Kinetics of Red Cell Pyruvate Kinase in Normal Individuals and in a Patient with Pyruvate Kinase Deficiency

Since the first report by Tanaka *et al.*[1] of non-spherocytic haemolytic anaemia due to pyruvate kinase (PK) deficiency, about twenty further cases have been reported. In patients with this type of haemolytic anaemia, determinations of PK give decreased, but not totally absent, enzyme activities. The remaining activity amounts to 5–20 per cent of the normal. Waller[2] first posed the question as to whether there was any real lack of enzyme or whether the disease was due to a structurally changed enzyme protein with decreased affinity to the substrate. He reported two cases where the Michaelis constant of the PK towards phosphoenolpyruvate (PEP) was significantly higher in erythrocytes of patients than in normal human beings.

In order to verify this hypothesis, we investigated the kinetics of the red cell PK of normal individuals and compared our results with those from a patient with PK deficiency, and his closest relatives.

Erythrocytes of the patient (an 8-year-old boy), of two heterozygous family members, and of healthy controls were washed several times with isotonic sodium chloride solution and haemolysed by distilled water. The haemolysate was partially purified by separating from haemoglobin, using DEAE and 'Sephadex *G*-100' chromatography. The Michaelis constants for PEP and ADP as well as the *p*H-optima were determined in the native haemolysate and in the haemoglobin-free eluate. Furthermore, the specificity of the enzyme was tested against coenzyme-analogues, using an equimolar concentration of inosine diphosphate (IDP), cytidine diphosphate (CDP) and guanidine diphosphate (GDP) instead of adenosine diphosphate (ADP).

The Michaelis constants for PEP and ADP before and after the purification are given in Table 1. These values as well as the determinations of coenzyme specificity of heterozygous carriers did not show any significant difference from the normals (Table 2).

Table 1. Michaelis Constants for PEP and ADP before and after Partial Purification by 'Sephadex *G*-100'

	PK i.u./g Hb	*Km* PEP × 10^{-4}		*Km* ADP × 10^{-4}	
		Native haemolysate	Purified eluate	Native haemolysate	Purified eluate
*p*H	7·5	7·5	7·5 6·5	7·5	7·5
Controls	4·5 ± 2·5	1·9	14 3·7	4·6	3·1
Patient	0·9	0·9	11	4·0	3·2
Father	3·6	0·6	16	2·5	5·0
Mother*	1·0	1·2	15 2·7	3·2	3·0
Brother J. P.	3·1	0·6	20 4·8	6·1	6·3
Brother M.*	1·2	1·0	17 4·0	2·7	6·5

* Probably heterozygotes.

Table 2. Coenzyme Specifity of the Red Cell Pyruvate Kinase

Percentual activities with coenzyme-analogues compared with those with ADP

	Native haemolysate				Purified eluate			
	ADP %	GDP %	IDP %	CDP %	ADP %	GDP %	IDP %	CDP %
Normal	100	65	47	< 5	100	42	36	< 5
Father					100	51	43	< 5
Mother	100	59	56	< 5	100	48	35	< 5
Brother J. P.	100	56	45	< 5	100	38	28	< 5
Brother M.	100	60	54	< 5	100	51	37	< 5

Most striking, however, was the fact that, after partial purification, the affinity towards PEP was lower in the eluate than in the native haemolysate—this was observable from the higher Michaelis constant, both in patient's and in normal erythrocytes.

This paradoxical behaviour was elucidated by the fact that the optimal *p*H after purification was 6·7 instead of 7·2—the *p*H at which all determinations had originally been performed. Repeated determinations of PK at this optimal *p*H in purified eluate resulted in Michaelis constants similar to those in total haemolysate. The

purification, however, had no effect on the Michaelis constant for ADP.

No difference could be demonstrated between the kinetics of PK of normals and of a patient with PK deficiency haemolytic anaemia. It seems, therefore, most unlikely that this disease is caused by an abnormal enzyme protein, but rather by a defect in the gene controlling the synthesis of PK in red cells.

Binding of Aromatic Compounds to Bovine Serum Albumin

The binding of non-ionic aromatic compounds to bovine serum albumin (BSA) has been approached in terms of the equilibrium between the bound and crystalline states[1]. The binding is quantitated in terms of the number of molecules of an aromatic compound solubilized per molecule BSA, in aqueous solution in equilibrium with the compound in its crystalline state. The measurement of this number, K, may be visualized as tantamount to the determination of the solubility of the compound in a two-dimensional solution on the surface of the protein molecule. This approach is derived from the interpretation of adsorption phenomena as thermodynamically analogous to solution phenomena[2].

Several mechanisms have been suggested for the binding of non-polar compounds to BSA and similar proteins. More than one type of interaction may be involved concurrently for the binding of a given compound; Benhold[3] has invoked two types, or degrees, of binding: (*a*) complete union of bound compound with the protein; (*b*) loose association, to interpret the solubilization of non-water-soluble physiological agents by BSA. Binding to BSA may be principally a function of interactions between a polar, functional group of the bound molecule and some group in the BSA[4]. Other investigators prefer to interpret the solubilization of non-ionic compounds by BSA in terms of hydrophobic bonding, principally[5]. In the light of this multiplicity of speculations regarding the mechanism of binding non-ionic compounds to BSA, the values of K, as defined here, were determined for a number of aromatic compounds. Possibly, the correlation of these values with the structural characteristics and physical properties of the compounds would yield some information on the mechanism or mechanisms of their binding to BSA.

The compounds investigated, their melting points and spectral characteristics are listed in Table 1. The preparation of *p*-phenylacetanilide[6] and *p,p'-bis*(*N,N*-dimethylaminophenyl)methane[7] was effected in this laboratory; the other compounds were obtained from the Eastman Kodak Co., and recrystallized as necessary. The number of molecules of each compound solubilized, that is, bound, per molecule of BSA, K, at 25° C and *p*H 7·5 (phosphate buffer, 0·1 M in total phosphate) was determined in the manner previously reported[1]. The values of K, as log K, are given in Table 2. This table also includes the solubilities of the compounds in the absence of BSA under the same conditions, x in moles per l. as log x.

Table 1. Properties of Compounds

Compound	Melting point (°C)	λ_{max} (mμ)	$\varepsilon \times 10^{-4}$
p-Aminobiphenyl	52–54	271	1·9
Naphthalene	82–83	276	0·54
Biphenyl	69–71	248	1·8
2-Aminofluorene	129–130	278	1·5
p-Phenylacetanilide	177–178	268	2·5
N-Acetyl-2-aminofluorene	203–205	276	2·5
Fluorene	116–118	260	1·8
Phenanthrene	101–102	293	1·4
p-Bromobiphenyl	90–91	260	2·1
p-Phenylacetophenone	122–123	283	2·4
p,p'-bis(*N,N*-Dimethylaminophenyl)methane	94–95	252	1·6
p,p'-bis(*N,N*-Dimethylamino)-benzophenone	178–179	375	3·3
Anthracene	218	252	11
2-Nitrofluorene	160	331	1·8

Table 2. Binding by Bovine Serum Albumin and Solubility of Aromatic Compounds at 25° C and *p*H 7·5

Compound	log K	log x
p-Aminobiphenyl	0·93	−3·2
Naphthalene	0·38	−3·8
Biphenyl	0·25	−4·6
2-Aminofluorene	0·23	−4·0
p-Phenylacetanilide	0·08	−4·2
N-Acetyl-2-aminofluorene	0·04	−4·7
Fluorene	−0·04	−5·0
Phenanthrene	−0·10	−5·4
p-Bromobiphenyl	−0·26	−5·5
p-Phenylacetophenone	−0·32	−4·9
p,p'-bis(*N,N*-Dimethylamino-phenyl)methane	−0·33	−4·9
p,p'-bis(*N,N*-Dimethylamino)-benzophenone	−0·58	−5·4
Anthracene	−0·83	−6·2
2-Nitrofluorene	−0·85	−6·3

Data in Table 2 suggest that the solubilization correlates with solubility; the calculated correlation coefficient for log K and log x is +0·96. A plot of log K as a function of log x is shown in Fig. 1. The regression line drawn according to the method of least squares represents the equation:

$$\log K = 0{\cdot}53 \log x + 2{\cdot}5 \qquad (1)$$

The simplest model for binding involves adsorption of the bound molecule on the surface of the BSA[8]. One surface of the bound molecule (assuming it is planar) is thus exposed to the solvent. In solution, both surfaces of the planar molecule are exposed to solvent, that is, water. There are, therefore, twice as many interactions between the molecule and water in the dissolved state as in the bound state. Thus, the contributions of these interactions to the energy of the molecule will be twice as great in the dissolved state as in the bound state. Since the solubility measurement compares the energy of the dissolved state, E_s, with that of the crystalline state, and K is a measure of the energy of the bound state, E_b, compared with the crystalline state, E_s and E_b should be related (if the entropies of the compounds compared are comparable in each state) according to equation (2):

$$\frac{dE_b}{dE_s} = \frac{d \log K}{d \log x} = \frac{1}{2} \qquad (2)$$

The experimental value of this derivative, obtained by differentiation of equation (1), is 0·53.

In the light of this relationship, it is of interest to note the results obtained in the earliest measurement of the solubilization, the increased apparent solubility, of slightly soluble compounds by serum proteins. The solubilization of anaesthetics in serum, compared with isotonic saline, reported by Moore and Roaf[9] shows this same pattern of increasing solubilization, s in concentration units, with

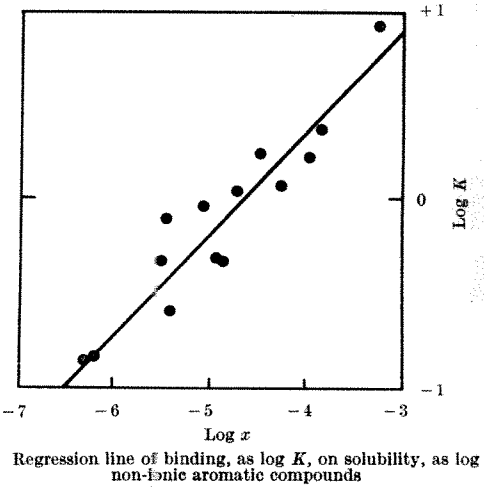

Fig. 1. Regression line of binding, as log K, on solubility, as log x, for non-ionic aromatic compounds

increasing water solubility of the anaesthetics. For these rather primitive data, a correlation coefficient of $c. + 0{\cdot}9$ may be calculated; $d \log s / d \log x$ (corresponding to $d \log K / d \log x$) is, as with the data reported in this communication, c. 0·5. This correlation, however, appears to have escaped the notice of the pioneer investigators.

The invocation of interactions such as dipole–dipole attraction, hydrogen bonding or compound formation between the bound molecule and serum albumin is, therefore, not necessary to the quantitative treatment of the binding behaviour of non-ionic molecules. The success of this simple interpretation is consistent with the visualization of binding as a consequence of hydrophobic bonding[5].

Tryptic Digestion of Tropomyosin *A*, Tropomyosin *B* and Myosin

Two types of tropomyosins co-exist in lamellibranch adductors and in cephalopod muscle[1]: TM_A and TM_B, TM_A being the protein referred to as invertebrate tropomyosin, or water-insoluble tropomyosin, by Bailey, and TM_B the water-soluble variety.

A prolonged action of trypsin on TM_A from *Pinna nobilis* has been examined[2]; besides dialysable products there remained a non-dialysable fragment which was precipitated by the addition of 3 per cent trichloroacetic acid (TCA). This fragment still contained a high proportion of arginine and lysine; its chemical and physical properties have been investigated[3]. When isolated under neutral conditions it proved to be highly resistant to further tryptic action. The rate and extent of the proteolysis were followed by different methods and the results indicated that trypsin splits approximately half the potentially susceptible bonds present in the whole molecule. Tryptic action on TM_A from other invertebrate species has now been investigated and it has been found to give a similar trypsin-resistant fragment which will be referred to as 'tryptic fragment'. TM_A was prepared from *Pecten maximus* adductor muscle by the ethanol method[1]. When hydrolysed with trypsin for 24 h under similar conditions to those used for *Pinna nobilis* TM_A (ref. 2), much diffusible material was obtained, leaving a non-dialysable fragment which precipitated after the addition of 3 per cent TCA. This fragment was isolated and purified by the same procedure as described for *Pinna* TM_A. The rate and extent of the digestion of *Pecten* TM_A with trypsin for 24 h at *p*H 8·2 and 25° C was followed by determining total nitrogen and α-amino nitrogen in the TCA-soluble fraction obtained after the addition of equal volumes of 3 per cent TCA to a portion of the digest, and by following the alkali uptake in the autotitrator. Table 1 shows the similarity of the effect of trypsin on *Pecten* TM_A and on *Pinna* TM_A, in rate and extent of the reaction. In both, about 50 per cent of the total nitrogen is TCA-soluble at the end of the reaction and the TCA-insoluble material still contains arginine[4]. In this case, as in the tryptic digestion of *Pinna nobilis* TM_A, changes in the enzyme–substrate ratio do not significantly affect the extent of the digestion (Table 1). The kinetics of the proteolysis was followed by alkali uptake in an autotitrator and found to be similar to that observed in the tryptic digestion of *Pinna* TM_A (ref. 4).

Table 1. Action of Trypsin on TM_A from *Pinna* and *Pecten*

	Protein conc. (mg/ml.)	Enzyme–substrate ratio (by wt.)	Conditions *p*H	Temp. (° C)	N in the TCA sol. as % of total N	Bonds split/mole (ninhydrin)	Bonds split/mole (autotitrator)
Pinna	4·3	16 : 100	8·2	25	59·4	144 (17 h)	—
Pecten	4·6	6 : 100	8·2	25	53·4	147 (18 h)	—
Pecten	5·9	0·9 : 100	8·2	25	63·0	—	—
Pecten	1·9	1 : 100	8·2	30	—	—	48 (2 h 30 min)
Pinna	3·4	1 : 100	8·5	30	—	—	52 (2 h 30 min)

The diffusible peptides produced by the digestion, when subjected to ionophoresis at *p*H 6·5, gave a pattern very similar to that obtained with the diffusate of the tryptic digest of *Pinna* TM_A. This is not surprising since the properties of *Pecten maximus* TM_A are in all respects very similar to *Pinna nobilis* TM_A (ref. 5). TM_A was also prepared from the South American mollusc *Aulacomya magellanica*; although it does not show such great similarity of properties with *Pinna* TM_A as *Pecten* TM_A it also leaves a trypsin-resistant fragment[4]. It appears, therefore, that the presence of a resistant tryptic fragment may be a general property of all tropomyosins *A*.

On the other hand, *Pecten maximus* TM_B (prepared by the method of Bailey and Rüegg[5] and kindly supplied by Dr. J. C. Rüegg) does not leave a fragment after digestion with trypsin for 2 h. No precipitate was obtained when the digest mixture was treated with either 3 per cent TCA or 0·1 N sodium acetate, *p*H 5·4 (conditions used for the precipitation of the TM_A tryptic fragment). After paper electrophoresis (0·06 M veronal buffer, *p*H 8·4) of the products of the digestion, staining with bromophenol blue did not show the characteristic blue band of the TM_A fragment. Furthermore, the peptide maps of these two proteins are very different (Fig. 1). Rabbit tropomyosin, which is thought to be similar to TM_B (refs. 5, 6), is also completely digested by trypsin (personal communication from the late K. Bailey).

So far, no TM_A has been found in vertebrate muscle, but molluscan muscle contains quite large amounts. The

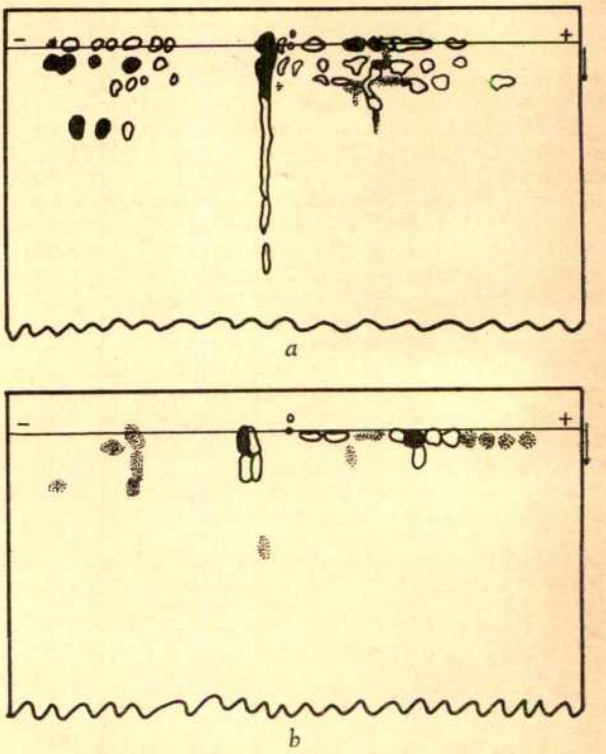

Fig. 1. Fingerprints of tryptic digests obtained by running a portion by descending chromatography in *n*-butanol–acetic acid–water (4 : 1 : 5, by vol.) for 17 h and electrophoresis under toluene in pyridine-acetate *p*H 6·5 for 1 h at a voltage gradient of 40 V/cm. Digestions were carried out for 2 h at 30° C, *p*H 8·2, enzyme–substrate ratio 1 : 100 (by wt.). Decreasing intensities of the ninhydrin colour, ■, □, ▩. (*a*) *Pecten* TM_A; (*b*) *Pecten* TM_B

properties of TM_A and myosin and certain features of their amino-acid composition have suggested[7,8] the possibility that vertebrate muscle contains TM_A as an integral part of the myosin molecule and not in a free form. If so, one would expect to obtain a 'tryptic fragment' similar to that obtained from TM_A, after tryptic hydrolysis of myosin. Experiments designed to test such a hypothesis were performed and it was found that although some TCA-insoluble material was obtained after digestion for 24 h, its solubility properties in ammonium sulphate were quite different from the TM_A 'tryptic fragment'. No material was precipitated at ammonium sulphate saturation exceeding 50 per cent (TM_A 'tryptic fragment' precipitates between 38–50 per cent saturation), suggesting that it is composed of smaller peptides.

The fact that the 'tryptic fragment' has been found in TM_A of three different species but not in TM_B suggests a structural characteristic which differentiates these two molecules. Whether this chemical characteristic is related to its functional properties remains to be seen.

Distribution of Chlorophylls in Chloroplast Fragments

THE molecular arrangement of the lipid-protein layers in chloroplasts, chloroplast grana, and smaller sub-units, is unknown but is vital to understanding the photophysical and photochemical events that occur there.

Recently, Boardman and Anderson[1] fragmented spinach chloroplasts with digitonin and showed a changing ratio of chlorophyll *a* to chlorophyll *b* in fractions separated by differential high-speed centrifugation. A fraction sedimenting between 50,000 and 144,000*g* had an *a*/*b* ratio of 6 and was interpreted to represent pigment system 1, the long wave-length system of photosynthesis. Fractions sedimenting at 10,000*g* or less had an *a*/*b* ratio of 2 and were interpreted to represent pigment system 2, the short wave-length system.

Murakami *et al.*[2] have also extracted spinach chloroplasts with digitonin and found a progressively increasing chlorophyll *a*/*b* ratio from 2·15 in whole chloroplasts to 12·0 in the supernatant after centrifugation at 105,000*g*. Their investigations showed reduced Hill activity and triphosphopyridine nucleotide reduction in the high-speed fractions suggesting that light-dependent reaction 2 was lost as particle size decreased. This was interpreted to mean that there was loss of an essential component(s), which, they point out, is supported by the concomitantly increasing chlorophyll *a*/*b* ratio, thus signifying loss of chlorophyll *b*.

We have mechanically fragmented spinach chloroplasts by sonication in an aqueous suspension rather than by using digitonin; fragment suspensions were then fractionated by differential centrifugation. The experimental conditions and centrifugation times have been published in detail[3–5]. The fractions (CF) are designated by subscripts indicating the centrifugal force range used to sediment the particular fraction. For example, CF_{1-20} is the fraction that pelleted between 1,000 and 20,000*g*.

Chlorophyll content was assayed in 80 per cent acetone and computed according to Arnon's equations[6]. Boardman and Anderson used Vernon's equations[7]. The method used by Murakami *et al.* is not reported. Thus the differences in absolute values between our results (Table 1) and theirs[1,2] may be due to the method of calculation or perhaps to inherent differences in the spinach. The highest *a*/*b* ratio occurred in CF_{70-145}, which corresponds to Boardman and Anderson's 50,000–144,000*g* fraction. The *a*/*b* ratio of 3 in the lower-speed pellet, CF_{1-20}, containing large fragments, corresponds fairly well to Boardman and Anderson's 1,000–10,000*g* fraction. The 145,000*g* supernatant ($CF_{145\ spt}$) shows a decreased *a*/*b* ratio relative to the CF_{70-145} fraction, which also agrees with the studies of the Australian investigators.

Table 1. CHLOROPHYLL CONTENT OF FRACTIONS ISOLATED FROM SPINACH CHLOROPLASTS

Fraction	Chlorophyll (mg)	Absorbancy ratio†	*a*/*b*
Chloroplast suspension	60·5*	2·56	2·74
CF_{0-1}	3·1		
CF_{1-20}	33·4	2·66	3·01
CF_{20-50}	16·4	2·73	3·25
CF_{50-70}	2·8		
CF_{70-145}	2·3	3·02	4·00
$CF_{145\ pts}$	1·5	2·82	3·32

* Average chlorophyll yield from 800 to 1,000 g wet weight of de-ribbed spinach leaves.
† Ratio of 663 mμ/645 mμ.

Preliminary investigations on small chloroplast particles sedimenting at 173,000*g* from $CF_{145\ spt}$ also showed a differential distribution of chlorophyll content. These small fragments, referred to as polyquantasomes, are photoactive[5,8].

Although the significance of these results is not clear, Boardman and Anderson's assignment of their 50,000–144,000*g* fraction to system 1 and of the remaining fractions to system 2 cannot be accepted unequivocally. The fraction sedimenting at 1,000–10,000*g* (system 2) is probably composed of particles greater than 1500 Å in diameter with an average molecular weight greater than 1×10^8 (refs. 5, 8). The fraction sedimenting at 50,000–144,000*g* is probably composed of particles 600–700 Å in diameter with an average molecular weight of 1×10^7 (refs. 5, 8). The sizes of all these particles are immense in comparison with quantasomes[9] or polyquantasomes[5], and the fractions are unquestionably composed of a considerable number of such sub-units. It is apparent that additional study of small-particle fractions is essential to establish firmly that the chlorophyll of spinach chloroplasts is associated with two different particles representing the two pigment systems.

Nevertheless, regardless of the fragmentation method, the changing chlorophyll ratios when correlated with the size of particles in the centrifuged fractions suggest that natural fault lines exist in the chloroplast lamellar structure along which rupture is most likely to occur when the organelle is subjected to chemical or physical stress.

This investigation has been supported by funds from IIT Research Institute, project *L*1012.

Glycogen Synthesis from Pyruvate in Muscle

Under normal conditions glucose is the major source of muscle glycogen. In muscle, pyruvate and lactate make only a minimal contribution to glycogen but the liver can freely convert these compounds into glycogen[1,2]. One of the key enzymes in the process of glycogenesis in liver is fructose-1,6-diphosphatase (FDPase)[3], and the inability of muscle to convert pyruvate to glycogen was attributed to its absence[4,5]. Recently, however, Krebs and Woodford[6] have shown that the enzyme does occur in striated muscle, so that at least one of the energy barriers in the conversion of pyruvate to glycogen is now known to be surmountable.

The possibility that muscle might be able to synthesize glycogen from pyruvate and lactate had to be considered when it was observed that the glycogen content of muscle, obtained from patients suffering from liver glycogen storage disease due to glucose-6-phosphatase (G-6-Pase) deficiency, was moderately but significantly greater than normal (Table 1).

In such patients glycogen is structurally normal and there is no enzymatic hindrance to the breakdown and removal of muscle glycogen. The observation was all the more unexpected because the blood sugar of these patients is low; on the other hand, the blood level of pyruvate and lactate is always high[7,8] (Table 1). It seemed possible, therefore, that under these circumstances these two compounds might become a source of muscle glycogen.

The supposition was supported when it was observed that considerably more radioactivity from labelled pyruvate was incorporated into the patients' muscle glycogen than into normal muscle glycogen (Table 2).

Additional evidence came from the assay of FDPase activity (Table 3) using the method described by McGilvery[9]. Some activity was detected in normal muscle but it was much greater in the muscle obtained from the patients, thus confirming the potential ability of muscle to form new glycogen from 3-carbon precursors.

For comparison, the results of analyses of muscle obtained from 2 patients suffering from a primary muscle glycogen storage disease, due to phosphorylase deficiency[10], are included in the tables. These patients do not have elevated plasma lactate and pyruvate levels and although their muscles contain more than the normal amount of glycogen, they behave like normal muscle with respect to glycogen synthesis from pyruvate.

These investigations confirm the presence of FDPase in human striated muscle. Krebs and Woodford[6] consider that its role in muscle is limited to the conversion of phosphorylated precursors, particularly α-glycerophosphate, because an energy barrier exists for the direct phosphorylation of pyruvate to phospho-enolpyruvate, and that it therefore plays only an insignificant part in the synthesis of glycogen from pyruvate. In the liver, this barrier is circumvented by the enzymes of the 'dicarboxylic acid shuttle'[11]; in this pathway, carbon dioxide combines with pyruvate to form oxalacetate, which is then converted, via malate, to phospho-enolpyruvate. In normal muscle, the activity of the enzymes of the shuttle is less than the sensitivity of the methods at present available for the assay[12]. However, the fact that not only pyruvate but also significant amounts of labelled bicarbonate (Table 2) can be incorporated into muscle glycogen under certain conditions suggests that they are probably also present in normal muscle. These vestigial pathways in muscle may become more active under the influence of high pyruvate and lactate concentrations and play a part in the metabolic homeostasis of the body.

Table 1

Condition	Subject No.	Age	Sex	Muscle glycogen (mg/g wet weight)	Blood lactate (mg/100 ml.)
G-6-Pase deficient		3	M	14	38
G-6-Pase deficient		4	F	18	42
G-6-Pase deficient		19	M	24	58

Conversion of Alcohol to Ethyl Esters of Fatty Acids by the Lactating Goat

Freshly secreted milk contains a lipogenic principle that will incorporate fatty acids into the ester lipids of the milk[1]. While investigating this principle with the aid of palmitic-1-^{14}C acid and thin-layer chromatographic analysis of the resulting labelled lipids, we noted a prominent spot on autoradiograms between the solvent front and the position of the triglycerides (Fig. 1). The position of this unknown substance was very close (following) to that of the cholesterol esters. It occurred to us that this spot might result from ethyl palmitate-1-^{14}C, since the labelled compound was dissolved in ethanol (usually 250 μl.) to facilitate dispersion in the milk. Further investigation confirmed this contention. The radioactive unknown substance exhibited R_F values similar to authentic ethyl palmitate with three different thin-layer chromatographic solvent systems. When the area of a plate containing the unknown was extracted and this extract injected on to an appropriate gas chromatographic column, 45 per cent of the activity measured in the unknown spot was trapped during the time ethyl palmitate would have emerged from the column. Since this recovery value results, in part, from losses in the syringe, in the column, by detector leaks, etc., the major activity is concluded to have moved in correspondence with ethyl palmitate.

Similarly, conversion of stearic acid to its ethyl ester was observed when it was dispersed with ethanol in the milk system, and both stearate and palmitate showed two closely moving spots when the ethyl esters were separated on thin-layer plates by a 60 : 40, hexane–benzene solvent system (data not shown). The capacity of the lipogenic milk system to convert stearate to oleate has been reported[2].

These findings regarding ethyl ester formation led us to consider *in vivo* alcohol metabolism and the problem of alcoholism. Two experiments were performed on each

of two lactating goats. In the first experiment 150 ml. of 30 per cent (v/v) ethanol in water was orally administered to the goats. Closure of the oesophageal groove was promoted by spraying the throat with 1 per cent copper sulphate, thus directing the alcohol to the abomasum and by-passing the rumen. Milk samples were recovered from the milk by extraction with 2 : 1 (v/v) chloroform–methanol. The lipid fractions eluted from silicic acid columns[3] ahead of the triglycerides, those containing the ethyl esters of fatty acids, cholesterol esters and hydrocarbons, were analysed by thin-layer and gas chromatography. Both goats showed evidence of ethyl esters in the milk lipids (Figs. 2 and 3 are representative). The maximum level of ethyl esters was reached in the 3–6 h period and approximated 0·01 per cent of the lipids in the case of one goat and about 0·001 per cent for the other. Milk collected the day following the experiment showed no evidence of ethyl esters. The characteristic pattern of fatty acid ethyl ester composition (Fig. 3), the component identities of which were confirmed on both polar (DEGS) and non-polar ('Apiezon-*L*') column coatings, closely resembles that of C_{16}- and C_{18}-fatty acids of milk fat. Although no short-chain fatty acid components were detected, we presume that ethyl esters were formed in the mammary gland. In the case of the goat showing the highest levels of ethyl esters in the milk, blood samples (25 ml.) taken at the same times as milkings (0, 1/2, 3, 6 and 24 h) showed no evidence of ethyl esters.

Somewhat anomalously the second type of experiment, in which 12 ml. of 20 per cent (v/v) ethanol in water was infused into the mammary gland by way of the teat canal, revealed no formation of ethyl ester by either goat in milk drawn at intervals over 24 h. From the odour of the milk drawn 30 min after infusion, rapid oxidation to acetaldehyde (and then to acetate) might account for the negative findings.

The foregoing results suggest that lactating human beings who consume alcohol might secrete traces of ethyl esters with their milk. Although we could not contrive that situation experimentally, we did analyse adipose tissue removed from eight adult human patients, several of whom admitted to moderate alcohol consumption.

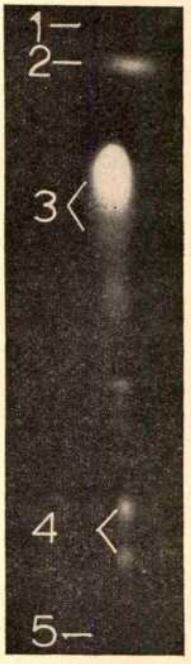

Fig. 1. Thin-layer chromatographic separation (autoradiogram) of neutral lipids from freshly secreted goat milk incubated for 90 min with palmitic acid-1-^{14}C (added in ethanol). 1, Position of solvent front; 2, ethyl palmitate; 3, triglycerides; 4, diglycerides; 5, position of origin. Solvent system 90 : 10 : 1 (v/v) petroleum ether–ethyl ether–acetic acid

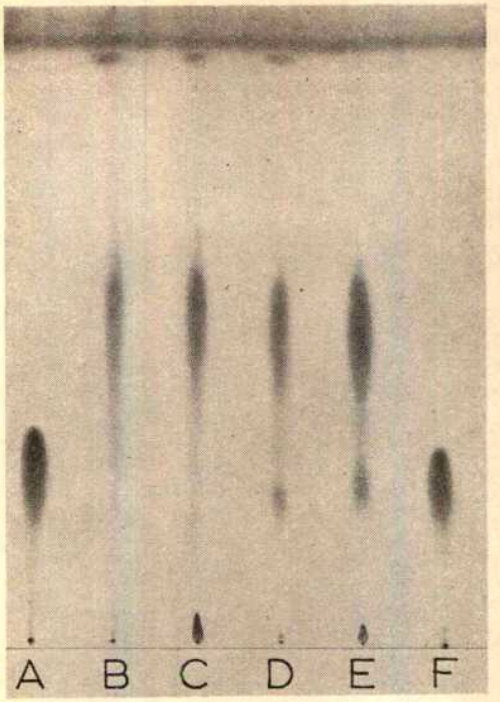

Fig. 2. Thin-layer chromatographic separation of goat milk lipids recovered in milkings 0 (*B*), 1/2 (*C*), 3 (*D*) and 6 (*E*) h after oral administration of a 'cocktail' (150 ml. of 30 per cent, v/v, ethanol in water) to the goat. *A* and *F*, Authentic ethyl oleate. Elongated spots (milk lipid samples) are from cholesterol esters. Solvent system 60 : 40 (v/v) hexane–benzene

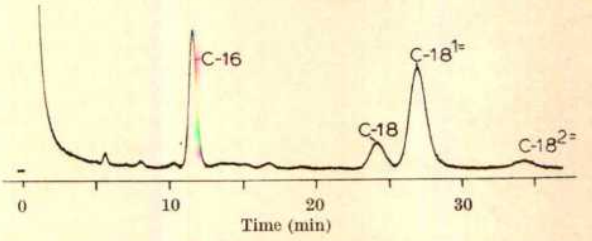

Fig. 3. Gas chromatogram of ethyl esters in goat milk lipids 3 h (see Fig. 2) after oral administration of alcohol to the animal. Peaks corresponding to ethyl palmitate, stearate, oleate and linoleate are designated C_{16}, C_{18}, $C_{18}^{1=}$ and $C_{18}^{2=}$, respectively

The tissue samples (primarily abdominal) were removed at the time of surgery and the lipids recovered and analysed by techniques described, preceding. Ethyl esters could not be detected in any of these samples. These negative results notwithstanding, a tissue by tissue analysis, especially of chronic alcoholics, might be rewarding.

In consequence of our present findings, previous activity data on cholesterol esters may be partly in error when we used ethanol to disperse label[1], but should be free of such error in experiments in which ethanol was not used[4,5].

We thank J. Reed Babcock, surgeon, Center County Hospital, Bellefonte, Pennsylvania, for the adipose tissue samples, and Robert J. Flipse, of our Department, for advice on autoradiography. PHYSIOLOGY

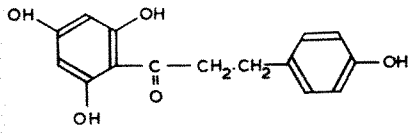
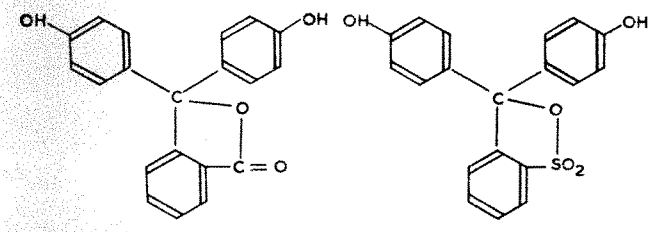
Polyphenolic Compounds and Intestinal Transfer

It is well established that phlorrhizin and its aglycone phloretin affect hexose transfer in a number of tissues. Recently Forsling and Widdas[1] showed that phenolphthalein caused competitive inhibition of facilitated glucose transfer in human erythrocytes. In view of its purgative action, it was of interest to test whether phenolphthalein also affected intestinal transfer mechanisms. At the same time the opportunity was taken to test another polyphenolic compound phenol red (phenolsulphonphthalein), a molecule of similar structure which is known to be transferred by the renal tubule. The formulae of these compounds are shown in Fig. 1.



Experiments were carried out with sacs of everted small intestine of the rat, as used by Barry, Matthews and Smyth[2], and the middle fifth of the combined jejunum and ileum was used in all cases. Glucose (28 mM) or methionine (15 mM) was initially present in the mucosal fluid and the transfer of these substances was investigated in the presence and absence of the polyphenols. The results are shown in Table 1.

In confirmation of Parsons, Smyth and Taylor[3], phlorrhizin (5×10^{-5} M) strongly inhibited glucose transfer, and at 5×10^{-4} M nearly abolished glucose transfer. As was found by Jervis, Johnson, Sheff and Smyth[4], phloretin (5×10^{-5} M) caused little inhibition, but we have now found that at 5×10^{-4} M it markedly reduced glucose transfer. Phenolphthalein (5×10^{-5} M) had almost as great an effect as equimolar phlorrhizin on glucose transfer, while phenol red even in a concentration of 10^{-4} M had little effect.



Any substance inhibiting transfer of glucose from the mucosal fluid may produce its effect either on glucose entry or on metabolism. These two activities can be separated by using glucose in the serosal fluid, as the glucose can then be metabolized without going through the entry mechanism. The effect of the inhibitor can be examined either by measuring fluid transfer (which depends on glucose metabolism) or by disappearance of glucose from the system. When glucose was present initially in the serosal fluid, phenolphthalein (5×10^{-5} M) did not affect glucose disappearance, and had only very slight, if any, effect on fluid transfer. Hence its action must be to prevent glucose from entering the cell from the mucosal side. Phloretin, however, reduced fluid transfer from 2·3 ml. to 0·4 ml., and this suggests that glucose metabolism was being impaired.

PHLORRHIZIN

PHLORETIN

PHENOLPHTHALEIN PHENOLSULPHONPHTHALEIN

Fig. 1

Table 1

Polyphenolic compound	Intestinal transfer: Glucose (μM)	Intestinal transfer: Methionine (μM)
None	337 ± 9(12)	61 ± 4 (10)
5×10^{-5} M Phlorrhizin	102 ± 7 (6)	62 ± 1 (7)
5×10^{-4} M Phlorrhizin	18 ± 3 (5)	41 ± 2 (6)
5×10^{-5} M Phloretin	307 ± 10 (6)	53 ± 4 (6)
5×10^{-4} M Phloretin	94 ± 6 (9)	22 ± 1 (6)
5×10^{-5} M Phenolphthalein	131 ± 12 (6)	36 ± 3 (8)
1×10^{-4} M Phenol red	317 ± 19 (6)	66 ± 3 (6)

Values given are the means ± *S.E.* The figures in parentheses indicate the number of experiments performed.

The effect of phenolphthalein is less specific than that of phlorrhizin as it inhibited methionine transfer in a concentration of 5×10^{-5} M, while a much greater concentration of phlorrhizin was required to cause a similar inhibition. Phenol red was also ineffective on methionine transfer in the concentrations tested. Phloretin (5×10^{-4} M) had more effect on methionine transfer than phlorrhizin in the same concentration, and this could be because its greater lipid solubility permitted easier entry into the cell with more effect on metabolism.

The difference between phenol red and phenolphthalein is of great interest on account of the similarity in their structure. A possible explanation is the difference in pK values. At a pH of 7·4 phenolphthalein will be mainly in the undissociated form, while phenol red will be largely dissociated, and the undissociated form may be the effective inhibitor of the entry process.

Comparative Study of the Urease in the Rumen Wall and Rumen Content

In the course of the ruminohepatic nitrogen cycle[1,2], or by supplementation in feeding[3], a considerable amount of urea can enter the rumen. The ureolytic activity of the rumen content was investigated and found to be due to some species of ruminal micro-organisms. Attempts to obtain enzyme preparations free from bacteria for a more accurate study, however, were unsuccessful[4]. Further investigations revealed that the urease activity of the ruminal mucosa appeared to be too high to be simply explained by surface contamination by rumen contents[5]. This communication deals with a study of partially purified urease preparations obtained from ruminal bacteria, as compared with partially purified enzyme prepared from the rumen mucous membrane, and the origin of the latter enzyme is also discussed.

Preparation of cell-free extracts. Washed suspensions of ruminal bacteria were prepared from the rumen content of freshly slaughtered cattle[6]. The bacterial cells were broken up using an M.S.E. ultrasonic disintegrator for 15 min. Cell-free extracts were obtained by centrifugation at 75,000*g* for 30 min. The mucous membrane from the rumen of freshly slaughtered cattle was washed thoroughly in a stream of cold water. The villi were cut off, homogenized in two parts of 0·1 M *tris*–HCl buffers (pH 8·5)

and finally centrifuged at 75,000*g* for 30 min to remove the cell fragments.

Preparation of acetone powders. Each cell-free extract was poured, with gentle stirring, into ten volumes of acetone chilled to −20° C. The precipitates were centrifuged down, washed twice by stirring with five parts of cold acetone and re-centrifuging. The washed sediments were suspended again in cold acetone and dried by suction on a Buchner funnel. The acetone powders could be stored in a desiccator at 4° C for several weeks without appreciable loss of activity. All the foregoing operations were conducted at about 4° C.

Preparation of enzyme containing solutions. The enzyme solutions of the acetone powders were prepared by extracting the corresponding powder in buffer by gentle stirring for 15 min. In the case of enzyme activity or *Km* determinations 0·2 M *tris*–HCl buffer (*p*H 8·5) was used. For *p*H-optimum estimations, 0·1 M *tris*-sodium monohydrogen phosphate–HCl buffers were taken. The amount of acetone powder to be extracted was chosen so as to give not less than 0·0015 Sumner units (S.U.)/ml. extract.

Measurement of enzyme activity. Urease activity was measured by incubating the corresponding enzyme solution with excess of substrate (0·04 M urea) in the outer chamber of a Conway unit. The final volume of the reaction mixture was 1 or 2 ml. in most experiments. The incubation period was 15 min at 20° C. The reaction was stopped by the addition of 1 ml. of saturated potassium carbonate. The ammonia produced was determined according to Conway[7]. Each determination was carried out in duplicate or triplicate against a blank. The urease activity measured in the acetone powders varied considerably according to the material used. Acetone powders from the ruminal mucosa contained about 0·0002 S.U./mg. The powders from the ruminal bacteria contained more activity, about 0·0005 S.U./mg.

*Effect of p*H. In Fig. 1 the reaction velocity is shown as a function of *p*H. Maximal velocity for both ruminal preparations is found at *p*H 8·5. The enzyme activity falls sharply on both sides of the maximum. Both curves are similar in shape. For comparison, soya bean urease was also examined. This preparation gave an optimum between *p*H 7·5 and 8·0. Here, the *p*H curve showed a more gradual fall on both sides (Fig. 1).

Effect of substrate concentration. The effect of urea concentration on the reaction velocity for each of the ruminal preparations is shown in Fig. 2. The Michaelis constants (*Km*) calculated according to Lineweaver and Burk were found to be $1{\cdot}5 \times 10^{-3}$ mol for both preparations. No difference could be detected between corresponding activities from purified ruminal bacteria and ruminal mucosa preparations. The *Km* of the soya bean urease preparation was $1{\cdot}57 \times 10^{-3}$ mol.

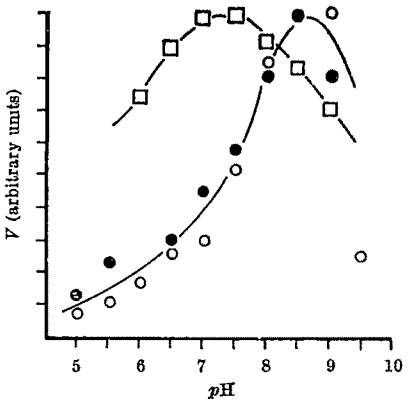

Fig. 1. The effect of *p*H on urease activity. The incubation medium (1 ml.) contained 0·1 mM *tris*, 0 1 mM sodium monohydrogen phosphate, hydrochloric acid added to give a *p*H as indicated, 0 04 mM urea, 0·4 ml. enzyme solution. Incubation period: 15 min at 25° C. ●, Enzyme preparation from ruminal mucous membrane; ○, enzyme preparation from washed bacterial suspension; □, enzyme preparation from soya bean powder

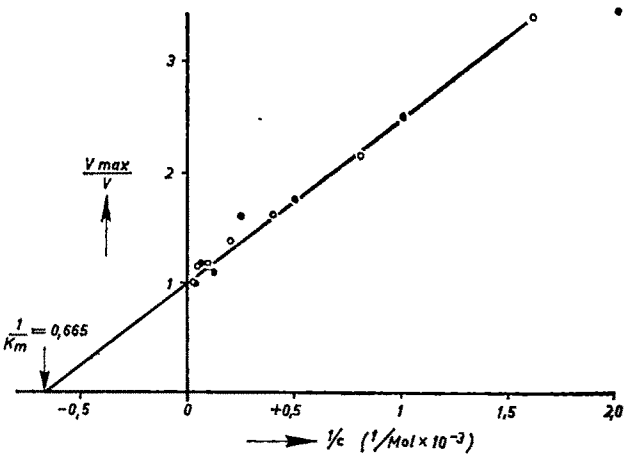

Fig. 2. The effect of substrate concentration on the reaction velocity. The incubation medium (2 ml.) contained 0·4 mM *tris*–HCl buffer *p*H 8·5, 1 ml. enzyme solution, and urea as indicated (*c*). See legend to Fig. 1 for additional explanations

These findings support the assumption that the urease activity of the ruminal mucosa originates from the rumen content. In order to confirm this assumption, experiments were conducted in which the mucous membranes were thoroughly washed with a detergent using a sponge. After this treatment the activity was found to drop to about 40 per cent. The rest of the activity could be detected in the wash solution. These results are in agreement with related experiments on the gastric mucosa of monogastric animals[8,9], in which it was shown that, in monogastric animals, urease activity is due to bacteria in the mucous membrane.

PHARMACOLOGY

Metabolism of Dimethyl Sulphoxide to Dimethyl Sulphone in the Rat and Man

Dimethyl sulphoxide (DMSO) was first prepared in 1867 (ref. 1), and has been known for some time to be an excellent solvent. However, the first report concerning its metabolic fate in animals appeared only recently, following several papers in which biological and even therapeutic uses for DMSO were suggested[2,3]. Distefano and Borgstedt[4] identified dimethyl sulphide in the expired air of cats given DMSO intravenously.

The present report describes the isolation and identification of dimethyl sulphone in the urine of rats and man given DMSO. (The results for rats were reported at the forty-ninth annual meeting of the Federation of American Societies for Experimental Biology, Atlantic City, N.J., during April 9–14, 1965 (ref. 5), and while this manuscript

was in preparation, isolation of dimethyl sulphone from the urine of rabbits given DMSO was reported by Williams *et al.*[6].) The metabolite was isolated from rat urine and identified as follows: twenty-four rats were dosed intraperitoneally with 0·5 ml./kg of DMSO. Urine was collected overnight in dry ice-cooled flasks, thawed and filtered through glass wool. The urine was extracted with heptane, which was discarded. (Experiments with urine from rats dosed with ^{35}S-labelled DMSO indicated that only traces of radioactive material were extracted by heptane.) The aqueous residue was then saturated with sodium chloride and extracted with chloroform. The extraction was repeated several times with fresh chloroform, and the combined chloroform phases were evaporated *in vacuo*.

The residue consisted of colourless needles and a pale yellow oil that were separated by filtration. Preliminary evidence indicates that the oil is essentially all DMSO (unpublished data). Recrystallization of the crystals from a mixture of heptane and chloroform yielded needles melting at 110·5–111° C. The melting point was not depressed on admixture with authentic dimethyl sulphone, m.p. 110·5°–111° C. Analysis (in per cent)—calculated for $C_2H_6SO_2$, carbon, 25·51; hydrogen, 6·43; sulphur, 34·07; found, carbon, 25·85; hydrogen, 6·49; sulphur, 33·98. The infra-red spectrum (in potassium bromide pellet) was identical to that of authentic dimethyl sulphone.

The excretion of dimethyl sulphone was quantitated by isotope dilution and 'reverse' isotope dilution in experiments in which rats were given 0·5 ml./kg of DMSO-^{35}S intraperitoneally. The results indicated that approximately 15 per cent of the dose was excreted in the urine as dimethyl sulphone within 24 h. A major portion of the dose of DMSO is excreted in the urine in this time[7]. Rats given dimethyl sulphone-^{35}S (21 mg/kg intraperitoneally) excreted 64 per cent of the dose in the urine in 24 h, apparently as unchanged sulphone, as shown by paper chromatography and thin-layer chromatography on silica gel (ethyl acetate).

Dimethyl sulphone was similarly isolated from the urine of a human subject receiving a daily dose of 21 g of DMSO. Elemental analysis, melting point and the infra-red spectrum were used to establish its identity. Isotope dilution analysis of the 24-h urine showed that the sulphone present represented 3·0 per cent of the daily dose.

Urinary Excretion of Acetylsalicylic Acid in Man

Mandel, Cambosos and Smith[1] have reported that appreciable amounts of acetylsalicylic acid can be present in human plasma and that it may be detected for up to 2 h after its oral administration. Also, from the work of Davison and Smith[2], the plasma proteins may bind acetylsalicylic acid to a much smaller extent than salicylic acid, thus making a greater proportion available for excretion. It should, therefore, be expected that some acetylsalicylic acid will be excreted in the urine.

The excretion of acetylsalicylic acid in urine after its oral administration has been the subject of a number of reports[3–7]. These have been based on the observed increase in the amount of salicylic acid which can be determined in the urine after mild hydrolysis. However, labile metabolites of salicylic acid which are also present in the urine will be hydrolysed to salicylic acid by the methods used, and the presence of acetylsalicylic acid cannot be conclusively established from such data.

The present investigations were undertaken after preliminary experiments had demonstrated that acetylsalicylic acid could be separated from salicylic acid and its metabolites in urine, by thin-layer chromatography (TLC) on silica gel (Merck *GF* 254). The developing solvent was benzene, ether, acetic acid, methanol (120 : 60 : 18 : 1) (ref. 8), and the following approximate R_F values were obtained for acetylsalicylic acid and its metabolites:

	Approx. R_F
Glucuronides of salicylic acid, etc.	0
Salicyluric acid	0·19
Gentisic acid	0·34
Acetylsalicylic acid	0·50
Salicylic acid	0·57

The acetylsalicylic acid on the chromatogram was detected in ultra-violet light as a dark band on the fluorescent background.

The excretion of acetylsalicylic acid in the urine of healthy young men, who had received an oral dose of the drug, was investigated. Urine collected at 1–2 h after drug administration was applied to the TLC plates as a narrow band. The chromatograms obtained from most of the urine samples examined gave a band corresponding to that obtained with an acetylsalicylic acid standard. To confirm the presence of acetylsalicylic acid, the urines were pooled, acidified to *p*H 2, and 200 ml. was extracted with ether.

Portions of the ether residue were applied to four 20-cm TLC plates and the bands corresponding to acetylsalicylic acid were scraped off into 5-ml. volumes of acetone. The acetone solutions were combined, centrifuged, and the supernatant reduced to a small volume which was applied to a TLC plate and re-developed. The appropriate band was removed and extracted with ether; the ether was evaporated to dryness after the addition of a little potassium bromide. The material isolated had an infra-red spectrum identical with that of acetylsalicylic acid.

A quantitative assessment of the amount excreted was made after the administration of acetylsalicylic acid (12 mg/kg body-weight) to six men. Urine samples were collected at 1·5 h intervals for 6 h after dosage. The 1·5 h urine samples were each diluted to 200 ml., and 0·3 ml. was applied to a 20 × 20-cm TLC plate and developed in the solvent system described. The acetylsalicylic acid band was removed from the plate into 5 ml. of N ammonia, mixed well for 20 min to allow solvation and hydrolysis to salicylic acid, centrifuged and the extinction of the supernatant measured at 295 mμ. Both blank urines and standard solutions of acetylsalicylic acid were subjected to the whole procedure.

The total salicylic acid content of the urine was also determined by the method of Brodie, Udenfriend and Coburn[9], after hydrolysis with 4 N sulphuric acid at 115° C for 3 h.

Table 1. Amount of Acetylsalicylic Acid excreted in the Urine of Six Men after Oral Dosage with Acetylsalicylic Acid (12 mg/kg Body-weight). Urines were collected at 1·5 h Intervals

Subject	Time after administration (h)	Amount of acetylsalicylic acid excreted: μmoles	Percentage of total salicylic acid *	Percentage of dose
A	1·5	72	16	1·9
B	1·5	22	10	0·5
C	1·5	28	11	0·6
D	1·5	111	19	2·6
E	1·5	0	0	0
F	1·5	89	22	1·7
	3	50	9	1·0 } 3·0
	4·5	17	2	0·3

No acetylsalicylic acid was detected in later samples.
* In the same urine sample.

The results (Table 1) show that acetylsalicylic acid was excreted in the urine of five of the six men taking part in this investigation. It was found only in the first 1·5 h specimens of four of the men, but was excreted for up to 4·5 h after its administration in one man. The average amount of acetylsalicylic acid excreted corresponded to only 1·5 per cent of the amount ingested.

HAEMATOLOGY

Prethrombin as a New Sub-unit of Prothrombin

Prothrombin is one of the important molecules concerned with the clotting of blood. It has been isolated from bovine plasma and characterized as a single molecular entity by means of ultracentrifugation[1], electrophoresis[2], electronmicroscopy[3] and N-terminal amino-acid analysis[4–6]. Under appropriate conditions of activation, this molecule yields two enzymes, namely, thrombin and autoprothrombin *C* (ref. 7). Other sub-units have been obtained by degrading the molecule with autoprothrombin *C* or thrombin, to obtain autoprothrombin I (ref. 8), or autoprothrombin II (ref. 9), respectively. Each of these functions as an accelerator in the conversion of prothrombin to thrombin. Another derivative called autoprothrombin III is inert[10], but is the precursor of the enzyme autoprothrombin *C*, which can be derived from autoprothrombin III with the use of tissue thromboplastin and calcium ions, or by activating with Russell's viper venom ('Stypven')[11].

We have now succeeded in obtaining another sub-unit of prothrombin which is the immediate precursor of thrombin, and we propose to call it 'prethrombin'. Its amino-acid composition as determined by a complete analysis with a Spinco amino-acid analyser was found to be similar to that of purified thrombin. Prethrombin concentration cannot be measured by the original two-stage procedure used for the assay of prothrombin. It becomes thrombin under conditions which we shall describe and then its specific activity is practically equal to the specific activity of purified thrombin. Probably only a small peptide or amino-acid needs to be removed to convert prethrombin to thrombin.

To obtain the prethrombin from the parent prothrombin molecule purified thrombin was used for the degradation. At *p*H 7·0 about 500,000 units of purified prothrombin were incubated with 25,000 U. of purified thrombin in a solvent volume of 40 ml. After 90 min practically no prothrombin remained and the protein was introduced into a DEAE cellulose column and chromatographed according to the procedure of Seegers and Landaburu[12]. The prethrombin was obtained in a separate fraction and autoprothrombin III issued from the column at a much later time as another separate fraction.

Based originally on the discovery of prothrombin by Alexander Schmidt, the view has been held that tissue thromboplastin and calcium ions are needed for the conversion of prothrombin to thrombin. About two decades ago, however, Ac-globulin was also found to be important in the activation. Now we find that prethrombin does not convert to thrombin in the presence of tissue extract thromboplastin, or in the presence of tissue extract thromboplastin plus calcium ions, or even if a concentrate of Ac-globulin is also added. Tissue thromboplastin thus has nothing to do directly with uncovering the active site(s) of the thrombin molecule. Tissue extracts are only concerned with the generation of autoprothrombin *C* activity[13,14]. We shall now describe experiments which show that autoprothrombin *C* is the enzyme that functions in prethrombin activation.

For the conversion of prethrombin to thrombin with autoprothrombin *C* no calcium ions or any other clotting factor was needed (Fig. 1). With the prethrombin substrate in excess thrombin generation depended on enzyme concentration. Zero-order reaction kinetics evidently applied. In each concentration of autoprothrombin *C* all the prethrombin was eventually converted to thrombin. For reasons not understood, there seemed to be an optimum autoprothrombin *C* concentration, and during the first 15 min thrombin generation tended to be retarded. The addition of purified thrombin at zero time did not alter the rate of activation by a given amount of autoprothrombin *C*.

In one of the experiments, 35 μg (160 U./ml.) of autoprothrombin *C* were mixed with 3,600 μg (11,000 U./ml.) of the substrate and 5 h was required for all the thrombin to generate (Fig. 1). This might be regarded as slow activation of the substrate. By adding Ac-globulin (purified according to the method of Aoki and Seegers[15]), cephalin and calcium ions, the activation was accelerated (Fig. 2). Instead of requiring 5 h, all was complete in 30 min with the ratio of enzyme to substrate at about 1 : 100. It was interesting that Ac-globulin did not accelerate the action of autoprothrombin *C* by itself; it only did so in the presence of cephalin and calcium ions. Cephalin and calcium ions, without Ac-globulin, retarded the generation of thrombin by autoprothrombin *C*, presumably because an autoprothrombin–calcium–cephalin adsorption complex formed. Such complexes have been described[16,17].

We conclude that autoprothrombin *C* is the enzyme concerned with uncovering the active sites of thrombin. This is not done by thrombin under the conditions of our experiments, nor by Russell's viper venom, nor by tissue extracts (Fig. 2). Furthermore, we were not able to bring about activation with purified platelet cofactor 1 (factor VIII) plus purified platelet factor 3 plus calcium ions, plus purified Ac-globulin. So autoprothrombin *C* seems to be the sole substance concerned with uncovering the essential thrombin sites of prethrombin. The activation of prethrombin with autoprothrombin *C* was completely inhibited by soybean trypsin inhibitor. Although trypsin is not a clotting factor thrombin activity was readily generated from prethrombin with trypsin; this is

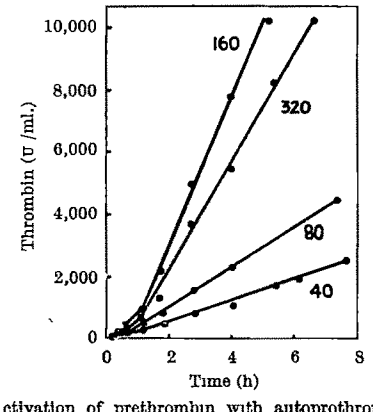

Fig. 1. Activation of prethrombin with autoprothrombin *C*. The prethrombin substrate concentration was 11,000 U /ml. in physiological saline solution buffered with imidazole *p*H 7·2 at 28° C. Numbers on curves indicate units of autoprothrombin *C*/ml. Specific activity of autoprothrombin *C* was 4,700 U./mg protein, that of prethrombin was 3,600 U./mg protein

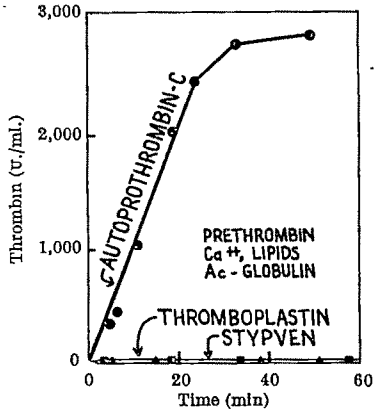

Fig. 2. Activation of purified prethrombin with purified autoprothrombin *C* in presence of calcium ions, lipids, and purified Ac-globulin. In all the activation mixtures the prethrombin substrate concentration was 3,000 U /ml. in 0 025 M calcium solution buffered with imidazole at *p*H 7·2. Concentration of purified Ac-globulin was 65 U./ml., and the cephalin 0·07 per cent w/v. Addition of 'Stypven' or tissue extract thromboplastin did not yield thrombin, but 50 U./ml. of purified autoprothrombin *C* produced rapid thrombin generation

of interest because it hydrolyses only peptide bonds the carbonyl group of which is associated with a positively charged side group (arginine or lysine)[18]. With the knowledge that the N-terminal amino-acid of thrombin is isoleucine[19,20] we can expect to find later that autoprothrombin *C* splits a peptide bond that is either arginyl-isoleucine or lysyl-isoleucine.

In 25 per cent sodium citrate solution, prothrombin becomes activated and thrombin and autoprothrombin *C* are formed by way of various intermediates[21]; either thrombin or autoprothrombin *C* can be used to stimulate the activation[7]. Prethrombin also became activated in concentrated sodium citrate solution; however, in this case, only thrombin activity was yielded. The reaction was rapid when primed with autoprothrombin *C*, but thrombin did not accelerate the reaction. Without autoprothrombin *C* the reaction was slow and usually the yields of thrombin were only 40 per cent of those obtained with autoprothrombin *C*.

IMMUNOLOGY

19S and 7S Antibody Production in the *Cyclo*phosphamide- or Methotrexate-treated Rat

Previously it was demonstrated that in a number of animal systems the primary antibody response is made up of two distinct phases[1–5]. The initial antibody appearing in the serum is a high molecular weight antibody, 19*S*. Later, the lower molecular weight 7*S* antibody appears and, as it rises, the levels of 19*S* antibody decline. Smith[6] and Svehag and Mandel[7] reported that X-ray treatment of normal rabbits resulted in prolonged 19*S* antibody synthesis, but it suppressed 7*S* γ-globulin synthesis. Smith[6] and Sahiar and Schwartz[8,9] reported that 6-mercaptopurine given to normal rabbits, while prolonging 19*S* antibody production, may also abolish 7*S* antibody synthesis. Blinkoff[10] noted a preferential inhibitory effect of methotrexate on 7*S* as opposed to 19*S* antibody production in the mouse.

Previously we found that *cyclo*phosphamide (CY) and methotrexate (MTX) markedly inhibited the ability of the rat to produce measurable antibody after the injection of sheep red cells[11], and that the timing of antigen injection in relation to drug treatment was of major importance in determining the amount of antibody produced. The investigation described here was designed to elucidate the effect of a 5-day course of CY and MTX given at various times in relation to intravenous immunization with sheep red cells.

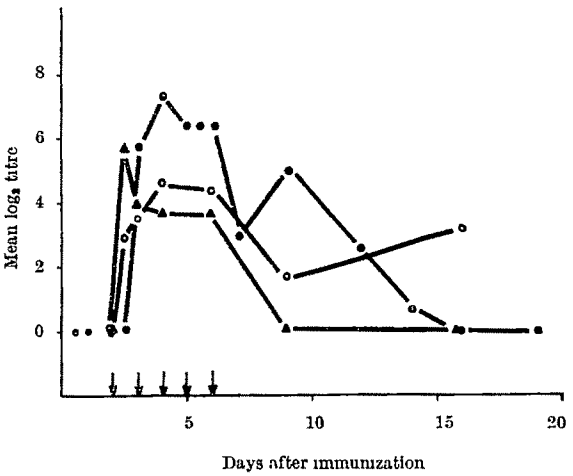

Fig. 1. 19*S* Antibody responses to sheep erythrocytes in rats treated with *cyclo*phosphamide or methotrexate 2 days after immunization. ●, 19*S* controls, ▲, *cyclo*phosphamide, 20 mg/kg × 5, (19*S*); ○, methotrexate, 0 75 mg/kg × 5, arrows indicate drug injections

Female Sprague–Dawley rats, 10–12 weeks old, were injected with 1 ml. of 10 per cent sheep erythrocytes, intravenously. Groups of animals were bled and killed 0·5, 1, 2, 2·5, 3, 4, 5, 5·5, 6, 7, 9, 12, 14, 16 and 19 days after immunization. Two other groups of animals were immunized similarly, but were given five consecutive and equal daily doses of CY (20 mg/kg) or MTX (0·75 mg/kg) intraperitoneally (40–50 per cent of LD_{50} for 30 days), beginning 2 days after immunization[11]. Four animals from each of these groups were bled and killed 2, 2·5, 3, 4, 6, 9 and 16 days after immunization, and the resultant sera titred. Total agglutinin titres were determined by two-fold dilutions in saline, as previously described[12]. Aliquots of each serum were diluted 1 to 2 in saline and incubated with an equal volume of 0·2 M 2-mercaptoethanol (2-ME) for 18 h at room temperature[12]. The remaining, or 2-ME resistant titre, was designated '7*S*' and the 2-ME sensitive

titre '19S'. Representative samples of serum were analysed with the sucrose density gradient centrifugation technique in a Spinco model *L*-2 centrifuge[13]. In all cases, the results of this analysis were in agreement with the 2-ME data. As an additional check on the density gradient technique, the presumed 19*S* and 7*S* fractions were subjected to immunoelectrophoresis with goat anti-rat globulin obtained from Hyland Laboratories, Inc.[14]. The geometric means of the titres for these three experimental groups are shown in Fig. 1. Data were analysed statistically by the method of Duncan and statistical significance accepted at the 1 per cent level[15]. The control animals first demonstrated 19*S* antibody 3 days after immunization. The peak titre was reached at 4 days. At 4 days, the first (see Fig. 2) 7*S* antibody appeared, and rose to its peak by the ninth day. At 14–19 days, the predominant antibody was 7*S*.

Animals treated with CY showed only a short 19*S* response, with an absence of 7*S* antibody. The MTX-treated group also showed no 7*S* response. In this case, however, even though the 19*S* peak was lower than the control, there was a persistence of significant amounts of 19*S* antibody after the control animals had ceased producing this type of antibody.

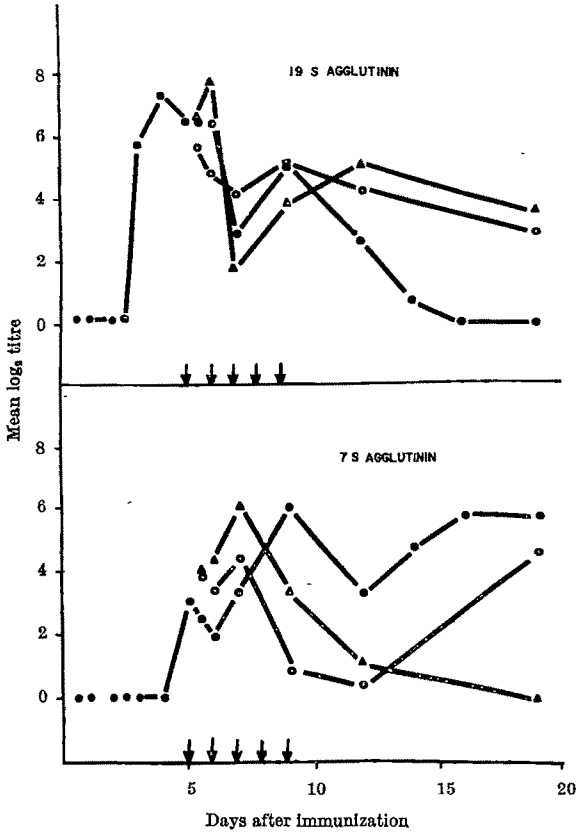

Fig. 2. Antibody responses to sheep erythrocytes in rats treated with *cyclo*phosphamide or methotrexate 5 days after immunization. ●, Controls; ▲, *cyclo*phosphamide, 20 mg/kg × 5; ○, methotrexate, 0·75 mg/kg × 5; arrows indicate drug injections

The effect of treatment with cytotoxic agents, beginning 5 days after immunization, is shown in Fig. 2. Drug-treated animals were bled 5·5, 6, 7, 9, 12 and 19 days after immunization. The data indicate that in CY- and MTX-treated rats 19*S* antibody production was significantly prolonged compared with the control. Production of 7*S* antibody decreased rapidly under the influence of both drugs. The delayed rise of 7*S* antibody after depression to very low levels in the MTX group suggests recovery from the effects of this drug. No such recovery was noted in these experiments for the CY-treated animals. The results of this experiment indicate that both agents can rapidly reduce 7*S* antibody production during its logarithmic phase of production while at the same time effecting a prolongation of 19*S* synthesis.

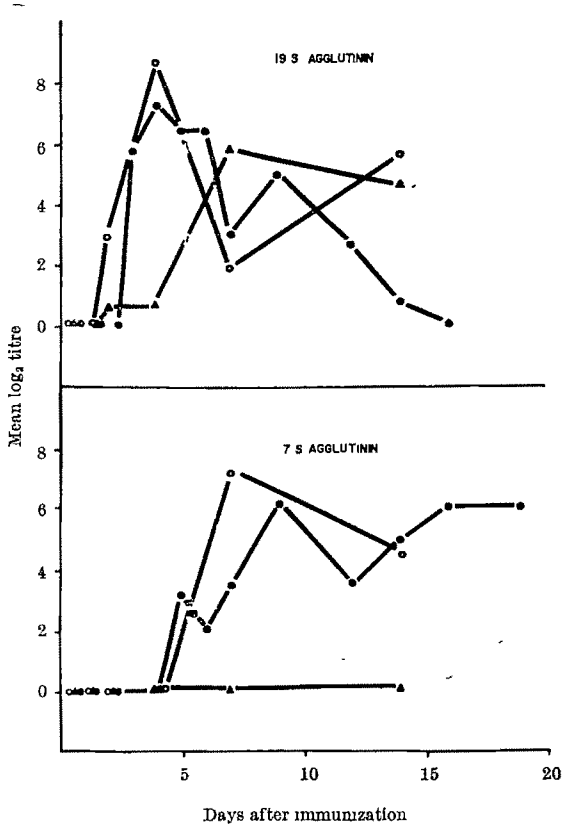

Fig. 3 Antibody responses in rats immunized with sheep erythrocytes 2 days after completion of a 5-day treatment with *cyclo*phosphamide or methotrexate. ●, Controls; ▲, *cyclo*phosphamide, 20 mg/kg × 5; ○, methotrexate, 0·75 mg/kg × 5

Fig. 3 depicts the effect of immunization beginning 2 days after completion of a 5-day course of either CY or MTX. Drug-treated animals were bled 0·5, 1, 2, 4, 7 and 14 days after immunization. The CY-treated animals showed no 7*S* response. The 19*S* production was delayed in onset, but prolonged. In the MTX-treated group, the 19*S* and 7*S* response was similar to that of the control, except for an elevated 19*S* antibody level at 14 days. The results indicate that pretreatment with CY can abolish the 7*S* response and result in a delay in the appearance of the 19*S* response. Pretreatment with MTX, on the other hand, does not produce these effects.

The present experiments, viewed in the light of the previous reports noted already, suggest that 7*S* antibody production in rodents is more susceptible to suppression than 19*S* synthesis by a variety of immuno-suppressive agents. Further generalizations must await the results of additional investigations with other drugs, antigens and species. It is hoped that experiments such as these, correlated with other parameters such as histological response, may lead to a better definition of the type or types of cells involved in 19*S* and 7*S* synthesis. The advantage of using immuno-suppressive drugs in order to study the possible interrelationships of 19*S* and 7*S* synthesis has been already emphasized by Sahiar and Schwartz[9].

A New Method of detecting Homograft Sensitivity

IN the course of studying the distribution of chromium-51-labelled lymph node cells injected intravenously or intraperitoneally into *A*-strain mice[1], it was found that the uptake of allogeneic and syngeneic cells differed in certain organs. This suggested that it might also be possible to detect differences of uptake between the tissues of control animals and of mice which had previously been sensitized to the donor strain antigens.

Cell suspensions were made from the peripheral and mesenteric lymph nodes of $(A \times CBA)F_1$ or *CBA* mice by the method of Billingham and Brent[2], except that Tyrode's solution, previously gassed with 5 per cent carbon dioxide in air, was used. Sodium chromate (^{51}Cr) injection, B.P. (Radiochemical Centre, Amersham, specific activity 50–150 c./g), was used to label the cells at a dose of 4 μc./10^8 cells by the method of Scalfe and Vittorio[3]. The cells were injected intravenously into mice at a dose of 5×10^6/g body-weight. In the first and second experiments $(A \times CBA)F_1$ cells were used and the recipients were adult *A*-strain animals.

In experiment 1 the recipients were: (*a*) unsensitized mice; (*b*) mice sensitized by grafting with *CBA* skin 4 weeks prior to testing and by intraperitoneal injection of 10^7 spleen cells 3 weeks later.

In experiment 2 the recipients were: (*c*) mice grafted with $(A \times CBA\text{-}T6)F_1$ skin 16 days prior to testing; (*d*) mice injected intraperitoneally with 10^6 or 10^5 $(A \times CBA\text{-}T6)F_1$ spleen cells 7 days before testing; (*e*) unsensitized mice.

In experiment 3 $(A \times CBA)F_1$ or *CBA* cells were injected into two groups of adult *CBA* animals. The recipients were: (*f*) unsensitized mice; (*g*) mice grafted with *A*-strain skin 12 days previously.

At intervals after injection of the test dose recipient animals were killed. Their tissues were removed and weighed; the radioactivity of the specimens was measured in a Packard 'Autogamma' scintillation counter.

In the first experiment (Table 1) unsensitized animals (group *a*) were compared with strongly sensitized mice (group *b*). At 24 and 48 h after injection of the allogeneic test dose the levels of activity in the spleens, livers, lungs, thymuses, grouped peripheral nodes, mesenteric nodes and salivary glands were determined. Table 1 shows the distribution of the dose in the spleens and peripheral nodes: the activity in the spleens was significantly higher in the unsensitized animals (twice that in the sensitized); and in the peripheral nodes it was four- to six-fold greater in the unsensitized mice (or four- to ten-fold when the greater weight of the nodes in the sensitized group was taken into account). A similar pattern was shown by the mesenteric nodes. There was a small, but significant, increase in the level of activity in the livers of sensitized animals. Little difference was observed in other organs.

Table 1. DISTRIBUTION OF $(A \times CBA)F_1$ LYMPH NODE CELLS INJECTED INTRAVENOUSLY INTO SENSITIZED AND UNSENSITIZED *A*-STRAIN MICE

Mesenteric nodes:				
Control	3 51 ± 0 205	6·55 ± 0·880	121 98 ± 10 17	195 90 ± 14 29
Sensitized	1·27 ± 0·279	7·34 ± 0·775	33·18 ± 7·31	197·75 ± 13·12

The second experiment (Table 2) was carried out to discover how far the loss of activity in spleens and lymph nodes ran parallel to the state of sensitization of the animal, by comparing mice which had received antigenic stimuli in doses known to elicit different degrees of immunity (groups *c* and *d*), as judged by skin-graft survival[4]. The spleens, peripheral nodes and mesenteric nodes of the various groups of mice were examined at 4 and 24 h after injection of the allogeneic test dose. Table 2 shows the distribution of activity in the spleens and peripheral lymph nodes at 24 h; the results for the mesenteric nodes and at 4 h were essentially the same as these. For both the percentage dose recovered and the putative number of cells per gram of tissue the figures exhibit lower levels of activity in the tissues of more strongly sensitized animals.

The third experiment (Table 3) was designed to establish the specificity or otherwise of the mechanism responsible for these differences. Here, sensitized and unsensitized mice (groups *f* and *g*) were compared in their treatment of allogeneic and syngeneic cells. The spleens, peripheral nodes and mesenteric nodes of the mice were examined at 24 h after the injection of the test doses. The tissues of sensitized and unsensitized mice show the same differences of activity following the injection of allogeneic cells as were observed in the first experiment; but virtually identical amounts are recovered in them following the injection of syngeneic cells. There are in fact slight

increases of activity in the sensitized group, attributable to the greater weight of the tissues.

These experiments thus demonstrate what appears to be immune elimination of allogeneic lymphoid cells (or immune elution of the chromium label) from the lymph nodes and spleens of mice presensitized to their antigens. They establish its specificity and show that the extent of elimination is related to the state of immunity in the recipients. The phenomenon may offer a useful method of measuring homograft sensitivity and is being further investigated.

Note added in proof. The paper of Najarian and Feldman (*J. Exp. Med.*, 121, 521; 1965), which appeared while this communication was in the press, substantially confirms these findings.

PATHOLOGY

Smell Threshold in Diabetes Mellitus

An elevated taste threshold for dextrose in diabetic patients without evidence of demonstrable diabetic neuropathy has recently been demonstrated[1]. Although it is unlikely that this was due to a non-specific decrease in gustatory acuity, those patients having normal thresholds for sodium chloride, further investigation of this possibility was indicated. The closely related olfactory threshold was, therefore, measured in 56 diabetic patients and 56 control patients, of the same age and sex. The method used was a modification of that of Elsberg and Levy[2], in which increasing quantities of an air–coffee mixture were released into the nose until the subject recognized an odour to be present (minimal perceptible odour). The modifications (to be described elsewhere) were designed to diminish important variables inherent in the original technique. The determination was carried out at the same time of day for each patient in a pair.

When the results were subjected to statistical analysis, the distribution of age and sex was unbalanced. A random sample, therefore, of two male and two female pairs were taken from each age group 20–29 . . . 60–69, and analysis of variance conducted on this sample. No significant difference was found between diabetic and control patients (Table 1). The only significant difference in both sets of patients ($P < 0.05$) was between age groups, although there was no obvious relationship between increasing age and threshold. However, thresholds of more than 30 ml. were not found under the age of 45 years, while thresholds of patients more than 60 years old varied from 5 to more than 80 ml.

Table 1. Mean of Olfactory Thresholds in 20 Pairs of Diabetic and Control Patients randomly selected from 56 Pairs according to Age and Sex

	Diabetic	Control	d	S.E. of d
Mean threshold (ml.)	14·7	16·9	2·2	3·6

This demonstration of normal olfactory thresholds in diabetic patients and the fact that their taste threshold for sodium chloride is normal[1] are against a non-specific decrease in gustatory-olfactory acuity in this disease. A second hypothesis to account for their abnormal taste threshold for dextrose would implicate tolerance to a raised level of blood glucose. This is unlikely, however, in view of the negative correlation which has been found between blood glucose-levels and taste threshold[1,3]. A third possible explanation which requires further investigation is that diabetic patients have an inborn defect of taste for dextrose.

We thank Prof. E. F. Scowen and Dr. K. O. Black for allowing us to study their patients, and the Board of Governors of St. Bartholomew's Hospital for financial assistance to D. S. P. One of us (P. T.) is in receipt of a Wellcome senior research fellowship in clinical science.

RADIOBIOLOGY

Uptake of Plutonium by the Lobster *Homarus vulgaris*

Because of its long effective half-life and its decay characteristics, and since it is deposited in bone, man-made plutonium is one of the more hazardous of the radioelements. It is released in exceedingly small amounts from nuclear fuel reprocessing plants and in nuclear weapons tests, and, like the long-lived fission products evolved in this way, it may be detected at low concentrations in the marine environment. The concentration of plutonium by marine organisms is, therefore, of some interest. The total α-content of the edible seaweed *Porphyra umbilicalis* and of fillets of the plaice *Pleuronectes platessa*, collected near Windscale Works, are given by Dunster *et al.*[1]. Some data on the contemporary plutonium content of Pacific Ocean sea water and the concentration factors in certain marine plants and animals collected near the southern California coast are given by Pillai *et al.*[2]. The concentration factor is the ratio of the amount of plutonium per g of tissue (wet weight) to the plutonium in the same weight of sea water.

Experiments on the uptake of plutonium-239 from aerated filtered sea water by lobsters were carried out in partitioned glass tanks in a room with a constant temperature of 9–12° C. Every few days the lobsters were transferred to fresh tanks of sea water containing $6{\cdot}5 \times 10^{-2}$ μc./l. of plutonium-239, until the initial rapid uptake of the isotope was completed, when the water was changed less frequently. During the experiment, the lobsters were fed on uncontaminated mussels.

All samples were dried at 110° C to a constant dry weight and ashed at 500° C for 16 h. Weighed amounts of the ashed sample were dissolved in 10 N nitric acid, and the plutonium extracted in the presence of ferric ion into 20 per cent tributyl phosphate/carbon tetrachloride. An aliquot of this extract was slowly evaporated on a large counting tray and its plutonium content determined on an α-scintillation counting unit.

The results show that when a lobster casts its shell, the soft shell, gills, hepatopancreas and flesh contain relatively less plutonium-239 than the normal animal, whereas the content of the cast shell is approximately twice that of the shell of the intermoult lobster (Fig. 1). The plutonium-239 in the cast shell was analysed, following ecdysis, 100 days after a lobster had been placed in the radioactive

water, and the tissues were analysed after 220 days. The results (Fig. 1) show that the calcifying shell accumulates plutonium-239 at a rapid rate. A very high proportion (89·5 per cent) of the total plutonium lies in the calcified skeleton which accounts for approximately 43 per cent of the total weight of the lobster[3]. The corresponding proportion present in the hepatopancreas is 4·6 per cent of the total plutonium. The flesh, which comprises approximately 28·7 per cent of the total body weight[3], contains only 1·2 per cent of the plutonium present in the whole body. The experimentally determined concentration factor of 3 for lobster flesh (Fig. 1) corresponds with the concentration factor of 3 for the fish *Sarda lineolata*[2].

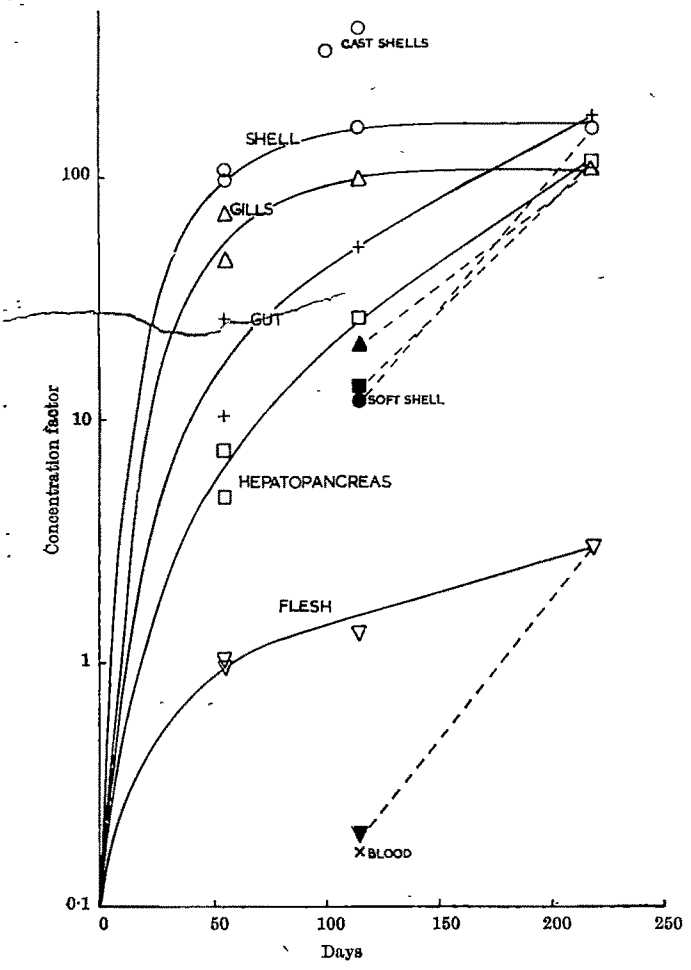

Fig. 1. Uptake of plutonium-239 by lobsters from sea water. Solid symbols represent the same tissues as do open symbols, from a lobster sampled immediately following ecdysis

Since the plutonium content of the flesh and hepatopancreas differs so markedly from that of the shell, it is advisable that edible tissues should be analysed separately if an assessment is to be made of the hazard to man in ingesting molluscs and crustaceans.

I thank the Torry Marine Laboratory, Aberdeen, in arranging for the supply of lobsters from Eyemouth.

BIOLOGY

Possible Path of Entry of Cations into Plant Cells

In a previous publication[1] some data were presented which were interpreted as indicating that Rb^+ ions move through the plasmalemma of barley root cells on a chain of fixed, negative sites of a macromolecule which probably make up part of a charged pore. The results suggested that this passage of Rb^+ through the membrane could be slowed down by less mobile ions like Na^+ or Ca^{++}. It was suggested, as a corollary, that if such be the case, the movement of a slow ion on such sites could be accelerated by a fast ion. To test this possibility, absorption rates of sodium-24 in the presence of a fast ion, such as K^+, were compared with those in the presence of a slower ion like Na^+.

Excised barley roots (*Hordeum vulgare* L., var. Trebi) were used to follow the uptake of sodium-24 in slightly acid or alkaline solutions of sodium chloride and potassium chloride. *Tris* (10^{-3} M) was used to raise the *p*H of the medium. Roots were excised from four-day-old seedlings grown in darkness at 22° C with calcium sulphate solution of 4×10^{-4} M concentration. They were washed several times with de-ionized water, carefully blotted with filter paper, and 0·5 g samples weighed. For salt concentrations of 10^{-4} M 300 ml. of solution and for higher concentrations 100 ml. of solution were used with each root sample. The radionuclide concentration was the same in all media. Plastic beakers containing the roots and absorption media were placed in a water bath at 22° C and continuously aerated. After an absorption period of 30 min, the roots were washed several times with 2×10^{-3} M sodium chloride and de-ionized water for about 10 min. Roots were then wet-ashed with concentrated nitric acid and perchloric acid. The residue was taken up in 10^{-2} N sulphuric acid and assayed for sodium-24 activity. The experiment was repeated several times. Some typical results from one experiment are presented in Fig. 1 on logarithmic scales and expressed as relative rates of sodium-24 absorption. Rates of total sodium absorption are given in Table 1.

Table 1. Rates of Total Sodium Uptake by Excised Barley Roots in the Presence of Sodium Chloride or Potassium Chloride

NaCl molar concentration	KCl molar concentration	*p*H of solution	Rate of Na uptake (μmoles Na/30 min)
10^{-4}	0	5·6	1·44
10^{-3}	0	5·6	2·53
10^{-2}	0	5·6	4·90
$5{\cdot}4 \times 10^{-6}$	10^{-4}	5·6	0·012
$5{\cdot}4 \times 10^{-6}$	10^{-3}	5·6	0·0059
$5{\cdot}4 \times 10^{-6}$	10^{-2}	5·6	0·0017
10^{-4}	0	8·4	2·09
10^{-3}	0	8·4	3·38
10^{-2}	0	8·4	5·76
$5{\cdot}4 \times 10^{-6}$	10^{-4}	8·4	0·136
$5{\cdot}4 \times 10^{-6}$	10^{-3}	8·4	0·041
$5{\cdot}4 \times 10^{-6}$	10^{-2}	8·4	0·0048

From Fig. 1 it can be seen that, as expected, the uptake rate of the radionuclide is reduced with increasing concentration of Na^+ ions in both acid and alkaline media, but the rates are considerably higher in alkaline media. At *p*H 5·6 and in the presence of K^+ ions, sodium-24 absorption is drastically decreased in comparison with that in the presence of Na^+. At *p*H 8·4, however, the results show that in this alkaline medium the drastic inhibition of K^+ ions is no longer seen. Now, sodium-24 is taken up at a faster rate in the presence of K^+ ions than when Na^+ ions are present. The part played by *tris* is believed to be chiefly in neutralizing H^+ ions. In media made alkaline with sodium hydroxide, results not presented here indicate that the faster rate with K^+ ions is also apparent to some degree.

Although the increased rate of sodium-24 uptake with sodium chloride in an alkaline medium could be due to increased affinity of absorption sites for Na^+ ions, interpretation based on certain considerations discussed in another paper[2] suggests that such is not the case here.

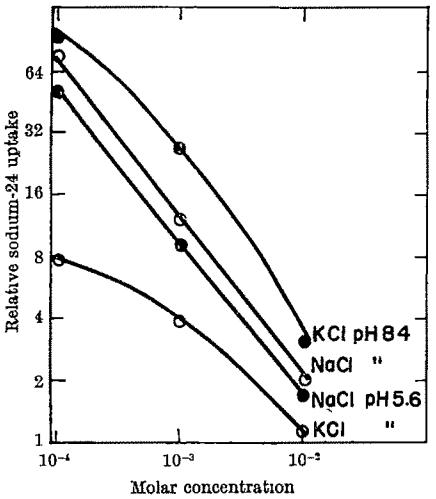

Fig. 1. Relative rate of uptake of sodium-24 by excised barley roots in the presence of sodium chloride or potassium chloride of varying concentrations and at two different *p*H's

Rate changes due to affinity changes should result in significant differences in the slopes of the sodium chloride lines in Fig. 1. Since the two lines do not show significant differences, the increased rate under alkaline conditions must be due to another cause—most probably to an increased accessibility of cation-absorption sites (a result of probable increase in pore size).

In the case of absorption in the presence of K^+ ions, it is suggested that two processes are operating at the same time: one is competition between sodium-24 and K^+ ions for absorption sites, and the other is an acceleration of the movement on a chain of negative sites of the slower sodium-24 ions by the faster K^+ ion. From results presented in the paper[2] previously cited, one would expect the rate of uptake of sodium-24 in the presence of Na^+ ions to fall on a straight line when log rate is plotted against log salt concentration. It can be seen in Fig. 1 that such is the case in both acid and alkaline media for sodium chloride. Now, since the reduction of the rate of uptake of sodium-24 by sodium ions is strictly due to competition for absorption sites, and if K^+ ions decrease the absorption rate of sodium-24 by only that process, the values in the presence of K^+ ions should also fall on a straight line. However, as can be seen in Fig. 1, in neither acid nor alkaline media do the rates fall along a straight line in the presence of K^+ ions. This non-linearity suggests that two processes are operating simultaneously in the presence of K^+ ions. One process is competition resulting in inhibition and the other could be an acceleration of the passage of sodium-24 through the plasma membrane by K^+ ions.

The data in Fig. 1 also illustrate the well-known phenomenon of preference of some plant roots for K^+ against Na^+ (figures for sodium-24 uptake in presence of K^+ ions at *p*H 5·6). Some investigators[4] have interpreted this specificity as indicating two different mechanisms or sites for the entry of K^+ and Na^+ ions into plant cells. One mechanism for both ions could be possible if ions enter plant cells through pores of varying sizes which are formed by a positively-charged protein and a negatively-charged macromolecule. If accessibility to external cation-absorption sites of the pores is determined by the protein, under acid conditions the attraction between the protein and the negatively-charged carrier could result in close juxtaposition of the two and thus limit the accessibility of cation-absorption sites. Under such conditions, a large and slow ion like Na^+ (hydrated) could displace H^+ ions from the cation-absorption site and be taken up fairly rapidly in the absence of any competing ion of lesser size and greater mobility. When such a competing ion is present, however, the absorption of Na^+ is drastically reduced due to the sites being more accessible to the smaller ion and due to the fast movement of the latter into the cell. On the other hand, under alkaline conditions the positive charges on the protein would be reduced, and the resulting diminished attraction for the cation carrier could result in increased pore size making sites more accessible. Under these conditions, a larger ion, especially if it has a strong affinity for this site, would have now a better chance of competing against a smaller ion. Additional evidence that a protein could be involved in accessibility of sites is the very marked effect of –SH inhibitors on the uptake of rubidium by mung bean root tips[5].

In view of the results presented in Fig. 1 and other results published previously[1], there is a strong possibility that cations enter plant cells through pores lined with negative sites. Such a movement of ions can be visualized as a case of exchange-diffusion along a chain of charged sites. The likelihood of a similar mechanism operating for anion uptake has been mentioned before[1]. Needless to say, a concept of a stationary, cation transport system would have advantages over the more popular hypothesis of a moving carrier. Harris[3] has discussed the possibility of movement of ions along such chains of charged sites in biological systems.

Increase in the Rate of Protein Synthesis with Age in *Drosophila subobscura*

Earlier work[1,2] on the life-span of *Drosophila subobscura* at different temperatures, and in particular of flies transferred from one temperature to another at various ages, led to the suggestion that as flies grow older their capacity to synthesize protein declines, until ultimately they are unable to replace the protein being lost by denaturation. This suggestion has been investigated by measuring the rate at which labelled leucine is incorporated into protein in adult males at different ages and at different temperatures. A parallel investigation is being undertaken of the incorporation of labelled uracil into RNA. These investigations are still being carried out, but some preliminary results on protein synthesis at a constant temperature are reported here; they show that changes in the protein synthetic mechanism are involved in the ageing process, although not in quite the way that had been foreseen.

The flies used were male F_1 hybrids between the *B* and *K* inbred lines of *Drosophila subobscura*, raised and kept throughout at the normal laboratory temperature of 20° C. Groups of five flies were etherized and weighed to the nearest 0·1 mg. As the flies started to recover from the ether, a fine glass pipette containing a solution of sucrose and tritiated leucine (5×10^{-4} molar leucine in 10 per cent sucrose; activity 0·5 mc./ml.) was held to their proboscis. In this condition, flies will readily drink any sweetened solution they are offered. A group of five flies can in 5–10 min be fed from 0·5 to 2·0 mg of solution, amounting to from 10 to 40 per cent of their unfed weight. After feeding, the flies were re-weighed to determine the amount of leucine they had imbibed.

Preliminary tests showed that label can be detected in protein perhaps within 5 and certainly within 10 min of the start of feeding, and that for periods up to several hours the amount incorporated is proportional to the time since feeding. This proportionality shows that the rate of equilibration between leucine in the haemolymph, and

the intracellular pool from which protein is synthesized, must be rapid. It was found convenient to kill and homogenize the flies 1 h after feeding.

The flies were homogenized in 10 per cent trichloroacetic acid and spun for 10 min at 3,000 r.p.m. The precipitate was then washed successively in 10 per cent trichloroacetic acid at 90° C, in ethyl alcohol at 60° C and in two washes of a lipid solvent (2 vols. ether, 2 vols. ethanol, 1 vol. chloroform) at 60° C. Immediately after the lipid solvent was removed, 0·5 ml. of water was added to the precipitate, which was then pipetted on to a ridged planchet; three further washings of the tube, using 1 ml. of water each, were added to the planchet. If this last procedure was carried out immediately after removing the lipid solvent, the precipitate remained finely divided and could be spread evenly on the planchet. The activity was then counted in a gas-flow counter. It is known that this washing procedure is effective in removing any unincorporated leucine; when unfed flies were homogenized and labelled leucine added to the homogenate, the protein extracted later from the mixture had an activity no higher than background

When labelled leucine solution was added direct to the planchet, counting efficiencies of from 23·3 to 28·0 per cent were obtained. But when labelled leucine was added on the planchet to the protein precipitate from five unfed flies, counting efficiencies varying from 6·4 to 12·2 per cent were obtained; a value of 10 per cent has been used in the calculations that follow.

Measurements[3] on an amino-acid analyser have given the following values per fly:

Free leucine	0·56 mμmole/fly
Leucine in small peptides	0·22 mμmole/fly
Leucine in protein hydrolysate	108 mμmole/fly

Since exchange between free leucine and small peptides is rapid, the best estimate of the leucine pool is 0·78 mμmole/fly. The size of the leucine pool was found not to vary significantly with age between 6 and 60 days of age. The amount of leucine fed to each fly was of the order of 10 per cent of the pool. Consequently, it was to be expected that the amount incorporated should be proportional to the amount fed, and this was found to be the case. Comparisons were therefore made in terms of counts per min per mg fed, although care was taken to feed approximately the same amount to all groups.

Protein synthesis in young flies. Since our interest was in the rate of protein synthesis in the non-dividing cells of adults of different ages, our results would be misleading if a significant part of the total protein synthesis in an adult male occurred in the testis—the only organ in which cell division occurs. Therefore, a comparison was made between the rate of incorporation in males lacking testes (the sons of females homozygous for the gene *grandchildless*) and their double first cousins who have testes; the results are shown in Table 1. The reasons for choosing cousins rather than *B/K* males as controls is that the *grandchildless* stock is necessarily highly inbred. It is concluded that the testis does not contribute a major part of the total protein synthesis.

Table 1

Type of male	No. of groups	C.p.m./mg
Lacking testes	6	2,920 ± 270
With testes	5	2,800 ± 160

Table 2

	Experiment 1		Experiment 2	
	No. of groups	C.p.m./mg	No. of groups	C.p.m./mg
1 h after feeding on labelled leucine	6	4,950 ± 350	—	—
25 h after single feed on 0·1 M leucine	6	7,030 ± 590	6	7,280 ± 980
50 h after second feed on 0·1 M leucine	—	—	7	6,250 ± 610

A large number of estimates are available of incorporation in young *B/K* males, since they have been used as controls in most experiments. The mean value is approximately 5,000 c.p.m./mg. If it is assumed that the total protein content of a fly is constant—and, in fact, little if any change occurs in 60 days—it can be calculated, using the values in the preceding section, that the proportion of protein molecules which are replaced in 1 h is approximately 1/3,000; the life-span of a fly at this temperature is approximately 2,000 h. This could mean that all species of protein molecules turn over very slowly, or more probably that most of the protein does not turn over at all, and that a small part turns over rapidly.

To settle this point, we have measured the rate at which label, once incorporated, comes out again once label has been removed from the free leucine pool. Groups of males were fed on labelled leucine solution, and then 1 h later fed approximately 0·4 mg/fly of unlabelled 0·1 M leucine solution. The second feed diluted the label in the pool by a factor of approximately fifty. However, when the flies were homogenized 25 h later, it was found that even after this dilution the rate of new incorporation was greater than the rate of loss of label from protein. Therefore, in a second experiment flies were given a second feed of 0·1 M leucine, 25 h after the first. Since measurements of free leucine have shown that excess leucine is excreted within 24 h, it follows that the two feeds together diluted the pool by a factor of 2,000–3,000. The flies were homogenized after a further 50 h. The results of these two experiments are shown in Table 2.

The drop from 7,280 to 6,250 c.p.m. represents the loss of label from protein in 50 h. The difference is not significant although it is in the expected direction. However, had the level of activity in protein dropped to half its initial value after 50 h, the experimental procedure would almost certainly have been accurate enough to show a statistically significant change. Hence, the experiment enables us to say that the mean survival time of those kinds of protein molecules which turn over most rapidly must be at least 100 h, and may be as great as 3,000 h.

Changes in incorporation rate with age. The most surprising results of these investigations have emerged from comparing incorporation rates in young and old flies. The result of the first comparison of this kind is shown in Table 3; the rate of incorporation is approximately twice as great in old as in young flies. This difference has been confirmed in several subsequent experiments.

Table 3

Age in days	No. of groups	C.p.m./mg
20	6	4,960 ± 610
60	7	9,660 ± 1,000

Measurements of free leucine show no consistent differences between young and old flies. Therefore the difference in incorporation rate demonstrates a difference in total rate of synthesis of protein: old flies synthesize protein at approximately twice the rate of young ones. The rate of incorporation of labelled uracil into RNA is also approximately twice as great in old as in young flies, but in this case we have no measurements of the uracil pool in old flies, so interpretation is less certain.

Two conclusions emerge. First, the mean survival time of even the most rapidly turning-over species of protein molecule is at least 100 h, and may be much greater. Secondly, the rate of protein synthesis is about twice as great in old as in young flies.

Although unexpected, the greater rate of protein synthesis in old flies could be explained if: (1) the rate of synthesis is determined, by way of a feedback loop, by the rate of loss of protein; (2) the rate of loss of protein is greater in old flies.

A greater rate of loss of protein molecules could arise either from a change in the physical and chemical environment in the cell, without a change in the primary structure of the protein molecules themselves, or from damage to the protein synthetic mechanism, leading to the synthesis of proteins with faulty amino-acid sequences. In either

case, our earlier suggestion that in old age flies die because they can no longer synthesize protein rapidly enough to replace losses may still be correct, although the cause of the imbalance may lie in an increased rate of loss rather than in a decrease in the maximum potential rate of synthesis; either process would account equally well for the data on life-span at different temperatures.

Development of *Boophilus decoloratus* (Koch, 1844) on the Ox

DURING a recent investigation of the post-larval development of the blue tick, *B. decoloratus* (Koch, 1844), using the chief host, the ox, at the Experimental Farm of the Animal Research Institute (that is, Achimota Farm), some interesting peculiarities in the habits and behaviour of this tick species were observed.

Eggs were obtained from engorged and mated females of *B. decoloratus* which were either collected from cattle in the field or bred in the laboratory or at the Achimota Farm. The laboratory-cultured eggs were kept in ordinary glass tubes, stoppered with cotton wool, and maintained over moist sand at a laboratory temperature ranging from 76° F (≏24·4° C) to 88° F (≏31·1° C). On hatching from the eggs, the larvae were allowed to harden at the usual laboratory temperature range before being placed on the host. The hardening time ranged between 2 and 10 days, average 6 days, approximately.

The larvae, contained in specimen glass tubes, were starved for more than 2 weeks after the cuticle had hardened, and were kept in the refrigerator at a temperature ranging from 59° F (≏15°C) to 68° F (≏20° C), during the period of starvation, to render them inactive. Before such larvae were used to infest the calf (No. 219), however, they were removed from the refrigerator and left for about 1 h on the laboratory bench to warm up and move about actively.

To infest the calf a sort of 'belly band' or 'trunk bag' was firmly secured around the trunk of the calf. The 'trunk bag' consisted of a piece of grey-baft cloth provided with a draw-tape at each end. The side seam of the 'belly band' had suitable fasteners for closing and opening it. During each infestation not more than 500 hardened and active larvae were placed direct on the dorsal and dorso-lateral aspects of the body of the calf, through the opening in the seam which was then closed up. The calf was tethered to a stake in the shade to ensure the development of the attached ticks under the prevailing field conditions of temperature and relative humidity (R.H., March, 66·5–91 per cent; April, 74–99 per cent; May, 72–95 per cent). The 'belly band' was removed 3 days after the infestation and any larvae which were found on the 'band' were destroyed.

The 'belly band' did not hinder the movement of the ticks on the host's body and immediately after the larvae were placed on the dorsal and dorso-lateral aspects of the body, under the protection of the 'band', several of them moved to various parts of the host's body, including the neck, head, ears and legs. The tethered calf became extremely excited and tried to rid itself of ticks by licking its legs. Many larvae dropped off the host and were lost, but some of them attached to the host's body within an average time of 1 h (range 30–120 min).

Doubtless many larvae did not complete feeding and could not develop into further parasitic stages because of certain adverse factors including inclement weather (rain) and loss through licking and brushing of the calf's body against the stake, after the 'trunk bag' had been removed. However, every effort was made to collect any fully-fed tick that dropped off the host. In certain cases in which it was expected that ticks which had taken the last blood meal would presently fall off the host, such ticks were specifically attended to until 18.00 hours, in order to collect them. The collecting of ticks, therefore, occurred intermittently between 0700 and 18.00 hours.

The larvae of *B. decoloratus* prefer the dew lap and neck, or else wander to the tip and outer pinna of the ear where they moult into nymphs. The nymphs remain at these sites to feed and moult into adults which migrate to the flanks and belly to feed[1–3].

Although the total number of adult females (36) which were collected was not quite large enough, I found that of this total the greatest number, seventeen, fed at the neck, ten at the back and flanks, five at the belly, one at each of the following sites: axilla, brisket, scrotum and head. Table 1 summarizes the result of the duration of development of the parasitic stages on calf No. 219.

Table 1. 1964 DATA ON DURATION OF DEVELOPMENT OF PARASITIC STAGES OF *B. decoloratus* (KOCH, 1844) ON CALF NO. 219

Mother tick No.	Date infesting with larvae	Adults dropped off	No. dropping off	Field temp. (° F) Range	Mean	Development from larva to adult
268	17 Feb.	9 Mar.	14	78–92	84·4	22 days
		10 Mar.	16	78–92	84·4	23 days
372	16 Mar.	7 Apr.	16	80–88	83·4	23 days
		8 Apr.	15	80–88	83·4	24 days
510	20 Apr.	12 May	15	78–88	83	23 days
		14 May	12	78–88	83	25 days
			Total 88		Average	23·3 days

(1) *Behaviour as a typical one-host tick species on bovine.* It will be seen from Table 1 that *B. decoloratus* showed the normal pattern of behaviour as a typical one-host tick and a total of 88 females developed from the larval through the nymphal to the adult stage on the same single host. These adult females were collected, on completion of development, when they dropped from the host. The average duration of development from larval through nymphal to the adult stage on the single host was found to be 23·3 days (range 22–25 days) at a mean average field temperature of 82·2° F (range 78°–92° F).

(2) *Behaviour atypically as a two-host tick species on bovine.* When some larvae, the progeny of gravid female tick No. 268, were fed on the calf on May 25, 1964, it was observed that as many as 56 dropped off the host after attaining full engorgement as nymphs and were collected within an average developmental period of 9·5 days (range 8–11 days) at a mean average field temperature of 83·1° F (range 78–92° F).

These nymphs were cultured in glass specimen tubes at the usual laboratory temperature ranging between 76° and 86° F (mean 79·9° F). In due course they moulted (*in vitro*) into adult ticks. The average premoulting period for 34 such nymphs was 19·8 days (range 18–20 days). The resulting adults hardened within an average period of 4·6 days (range 2–6 days). Ten of the females derived from this stock of ticks were then placed on the calf for rearing. After 3 days, however, they all detached without becoming even partially engorged[4].

The sites of predilection of the adults of the blue tick were easily noticed when the ticks were about to take the last blood meal, and especially at the stage of full engorgement. Usually the last blood meal was imbibed within 2 or 3 days prior to detachment. In addition to the result already presented on the subject of preferred feeding sites, it is noteworthy that I found 68 females of *B. decoloratus* feeding at various points on the groin and inner parts of the hind legs of four calves (that is, an average of 17 female ticks per calf). I also observed in twenty cases that the male often fed at the same locus as the female, and the ventral aspects of their bodies were in contact. Thus, apart from the flank and the belly, the adult blue tick can also feed at other loci.

Hard ticks show a wide range of adaptability to their hosts, ranging from species which are confined to one host to those which show little or no preference for hosts above and including reptiles[3]. Several workers, notably Hoogstraal[1], Arthur[2,3] and Theiler[4], have stated that the blue tick is a one-host tick. Matthyse[5] has reported that all the parasitic stages of the blue tick occur on cattle throughout the year. Theiler[6] confirmed that the life-cycle of this tick species was completed entirely on this host, except for oviposition. Lewis[7] has also stated that the blue tick completes its life-cycle as a one-host tick. Finally, Loundsbury[8] has recorded that the engorged females detach in 23 days after attaching as larvae. In regard to this particular behaviour of the blue tick as a one-host tick species on the ox, my experience is quite the same as that of the aforementioned authors. However, this communication does seem to report for the first time the occurrence within the genus of a remarkable departure from this typical behaviour: namely, the peculiar behaviour of *B. decoloratus* as a two-host tick species. Hitherto all the three members of the genus (*B. decoloratus*, *B. annulatus* and *B. microplus*) have been described as being characteristically one-host tick species[1–3].

On account of this peculiar behaviour of some individuals of the blue tick, it is inferred that instead of transforming into adults at the sites already selected by the larvae, some engorged nymphs of this tick species detached, wandered about for some time and dropped off eventually to moult into adults. If the nymphs had had opportunity to moult in sheltered areas in the immediate natural environment of the calf, the resulting adults would no doubt have sought the host a second time in order to feed.

I thank the Ghana Academy of Sciences for the opportunity and facilities to carry out this work at the Animal Research Institute.

A Method of Isolating and Counting *Nippostrongylus brasiliensis* from Unweaned Rats

Methods for the recovery and counting of adult *Nippostrongylus brasiliensis* from the intestines of adult rats have been described by Jennings *et al.*[1] and Ogilvie[2]. Such methods need to be very accurate, particularly where estimations of the degree of immunity of the host are to be made on the basis of such counts. The techniques described by these authors have been used routinely in this laboratory during experiments on adult rats and have proved quite satisfactory. However, on application to the recovery of worms from the intestines of neonatal or unweaned rats a number of difficulties were encountered.

Because of their small size and delicate structure, opening the intestines of very young rats with scissors is an extremely difficult procedure and can result in a significant loss of worms. The consequent spread of intestinal contents around the site, on instruments, etc., requires repeated rinsing for the recovery of worms, so that they are eventually collected together for counting in an excessive quantity of fluid. Such a method is particularly unsatisfactory during the early stages of an infection when immature forms, not visible to the naked eye, are present. These difficulties are eliminated in the method described here.

The abdomen is opened and the posterior oesophagus cut; the stomach is then loosened from its surrounding attachments and the small intestine gently unravelled, particular care being taken in the region of the pancreas and caecum, where the intestine is most likely to break. It is then threaded on to a glass rod of 5 mm diameter, one end of which has been drawn out and the tip heated to a ball of such size that it easily enters the lumen of the intestine. The whole small intestine splits open during this procedure, and it is then transferred to a 1-l. beaker containing N saline at 37° C. The gloved fingers of the operator and the glass rod are rinsed with saline into the same beaker, until no traces of intestinal contents remain. The contents of the beaker are then drained through a double layer of surgical gauze spread over the top of a second beaker so that the intestine is retained in the gauze. The first beaker is repeatedly rinsed into the second. The gauze is then caught up on a glass rod so that the intestine is suspended in the saline. The beaker is left in a water bath at 37° C for 1 h, by which time the worms have penetrated the gauze and are lying at the bottom of the beaker, in 500 to 1,000 ml. of saline.

The contents of the beaker are filtered through a Büchner funnel using Green's 'Hyduro 904', 18·5 cm diam. filter paper, which has been previously marked off in 8 mm squares on a duplicating machine, with repeated rinsing to ensure that all the worms are transferred from the beaker to the filter paper. By adjusting the flow from the beaker the worms are spread evenly over all but the periphery of the filter paper.

The filter paper is removed and, if the worms are required only for counting, is allowed to dry completely. The worms are easily visible as red coils adhering closely to the paper, and are counted at a magnification of 12·5 × using a binocular microscope. The 8-mm squares on the filter paper act as convenient guidelines.

If the worms are required alive, the filter paper, while still wet, is laid for counting on a sheet of 'Perspex' 20 cm in diameter. Afterwards the filter paper is inverted over a 1/16th in. mesh sieve on top of a filter funnel containing normal saline at 37° C and fitted with a tap. The worms descend through the saline and collect in the narrow stem above the tap, from where they can be run off into a stoppered measuring cylinder to the required dilution.

A Periodicity of Tritiated-thymidine Incorporation into Cytoplasmic Deoxyribonucleic Acid during the Cell Cycle of *Tetrahymena pyriformis*

Reports indicate that ^{3}H-thymidine is incorporated into a DNase-sensitive material in the cytoplasm of the ciliate *Tetrahymena pyriformis*[1–5]. It is now known that most of this cytoplasmic DNA is localized inside the mitochondria of this species[1]. Furthermore, this cytoplasmic DNA appears to be stable and conserved during cell growth and reproduction[1,4].

The purpose of this communication is to establish whether or not a relationship exists between cytoplasmic DNA replication and the DNA replication in the micro- or macro-nucleus of the cell. *Tetrahymena pyriformis* strain

HSM is known to replicate its micronuclear DNA during a half-hour period at the time of cell division, whereas the macronucleus replicates DNA for about 1 h during the middle of the cell cycle[6]. Thus the two nuclei replicate DNA independent of each other[6,7].

The cells were grown axenically in a defined medium plus 0·04 per cent proteose peptone (see ref. 6 for details). The cells have a generation time of 225 min in this medium. Cultures of these cells, in log growth, were exposed to ^{3}H-thymidine 20 μc./ml. (sp. act. 6·7 c./mmole) for 15 or 30 min, air dried on slides, washed with cold 0·5 N perchloric acid and 3 : 1 ethanol–acetic acid, and prepared for autoradiography[6,8]. Some slides were treated with DNase prior to autoradiography. At least 2 weeks of autoradiographic exposure were necessary to increase cytoplasmic grain counts to a measurable level.

Both cytoplasmic and nuclear radioactivity were removed by DNase digestion. Analysis was performed on cells which were classified into three groups: (1) with a labelled macronucleus; (2) with a labelled micronucleus; (3) without nuclear labelling. An ocular grid was placed over an area of cytoplasm, at some distance from either nucleus, and the silver grains were counted.

The average grain counts per unit area for seven individual experiments, corrected for background, are listed in Table 1. The individual and pooled tests of equality of the following categories of cells are shown in Table 2: (1) without macronucleus labelled versus micronucleus labelled; (2) macronucleus labelled versus micronucleus labelled; (3) without macronucleus labelled versus macronucleus labelled. When the individual t values are pooled, as shown in Table 2, the following conclusions are warranted: The incorporation of ^{3}H-thymidine into cytoplasmic DNA is higher during micronuclear DNA replication than during any other part of the cell cycle. Comparison of ^{3}H-thymidine incorporation into the cytoplasmic DNA of cells without macro- or micronuclear label and cells with a labelled macronucleus show no significant difference. With but few exceptions, the individual tests of equality in the different experiments showed that the cytoplasmic DNA label is significantly above background throughout the cell cycle.

Short exposures of cells to ^{3}H-thymidine were used because longer exposures would allow appreciable numbers of cells to pass from one part of the cell cycle to another and would therefore confuse the classification of cells and subsequent interpretations. An increased ^{3}H-thymidine incorporation into cytoplasmic DNA at the beginning of macronuclear DNA replication has been observed in this laboratory and elsewhere[1]. Apparently, this increased rate of incorporation is of such short duration that it has been missed by my method of analysis, which sums the grain counts during all the macronuclear DNA-synthetic period.

§ See ref. 9.

Cytoplasmic DNA synthesis occurs during most if not all of the cell cycle. The increased cytoplasmic incorporation of ^{3}H-thymidine which occurs during micronuclear DNA synthesis and which is also observed at the beginning of the macronuclear DNA-synthetic period may reflect an increased rate of cytoplasmic DNA synthesis at these times in the cell cycle. Alternatively, the increased incorporation may reflect a change in the size of deoxyribonucleotide pools which occurs at these two times in the cell cycle. The findings suggest that there is an interdependence between nuclear DNA synthesis and cytoplasmic DNA synthesis.

Re-examination of the Effect of Daily Rotation in the Horizontal Plane on Growth of Cyclamen Plants and Etiolated *Avena* Seedlings

Jones[1], in New Zealand, has reported that rotating cyclamen and bean plants in a clockwise direction about a vertical axis at one revolution per day resulted in a loss of turgidity and accelerated the death of leaves, whereas normal growth was maintained when the direction of rotation was anti-clockwise. In other experiments it was shown that when etiolated *Avena* seedlings were rotated in darkness in the same manner, clockwise rotation caused a reduction in root and shoot extension growth, while, by contrast, anti-clockwise rotation brought about increased growth. Jones did not interpret these results, which were reported as being distinct and unequivocal, and they do not appear to be gravitational or centrifugal responses. However, Jones's technique of slowly rotating plants about a vertical axis has recently been used[2,3] in experiments to support claims that in some plants, notably cereals, growth and root orientation is affected by the horizontal component of the magnetic field of the Earth. To seek independent confirmation of Jones's findings, similar experiments have been carried out in Griffith, Australia, at latitude 34·18° S., using cyclamen and etiolated *Avena* seedlings. Negative findings are reported here.

Cyclamen. Three single cyclamen plants (*Cyclamen persicum* Mill.), growing in metal cans, were each placed on a horizontal, clock-driven turntable, so that the plants rotated about their own axes in a clockwise direction at a rate of one revolution a day. The three plants, together with stationary controls, were kept in a lightly shaded unheated glasshouse throughout the winter months of July and August, this being the most favourable time for growth of cyclamen in inland Australia. The experiment

was continued for 7 weeks, during which period all the plants flowered.

No symptoms indicating abnormal growth or development could be detected among the rotated plants. The effect of anti-clockwise rotation was not re-examined.

Avena. Husked oats (*Avena sativa*, variety Burke) were soaked overnight in tap-water in darkness at 5° C, and then sown in two shallow trays on moist facial tissue with the embryo facing upwards. Each tray contained 40–50 seedlings. Using a clock-driven turntable, with a vertical axis, one tray was rotated in either a clockwise or anti-clockwise direction at one revolution a day. The non-rotated tray served as a control. The experiments were performed at 25° C and high relative humidity inside a metal incubator, which was kept in a constant-temperature darkroom so that all operations and inspections could be carried out in green light of predominantly 546 mμ. After 3 days the length of the shoot (coleoptile and mesocotyl) and the longest root of each seedling was measured to the nearest millimetre. Seven clockwise replicates, followed by eight anti-clockwise ones, were performed at weekly intervals.

Rotation of the seedlings in either direction produced no visible effects. The percentage mean difference between shoot and root lengths of stationary and rotated plants is shown in Table 1. With one exception, the extension growth of the root and shoot of the rotated plants did not differ significantly from that of the stationary plants, in any of the replicates. These results are in contrast with those of Jones, where in nine replicates the average reductions in coleoptile and root final length in clockwise rotated plants were 6·1 and 8·6 per cent respectively, while the corresponding average increases in anti-clockwise rotated plants were 5·6 and 10·2 per cent. Furthermore, the direction of rotation produced a consistent response in each replicate. Jones used a 5-day rotational period, while the results summarized in Table 1 are for a 3-day period; nevertheless, the plants were growing actively throughout the 3 days, so that an appreciable effect of rotation on the elongation rate of the shoot or root should have been apparent by the third day. Despite the absence of a significant response to rotation in the majority of replicates, examination of Table 1 shows that in each of the first seven, where the plants were rotated clockwise, the shoots grew less than those of the controls. Since the trend of this difference is in agreement with Jones's conclusions, the effect of clockwise rotation on the extension growth of the etiolated shoot of the *Avena* seedling was further examined in a second experiment, in which the experimental technique used by Jones was more closely followed.

Avena seedlings were germinated using the method already described here and kept under the same environmental conditions as in the previous experiment. On the second day, the seedlings were transferred from the shallow trays to two perforated plastic holders each holding thirty seedlings, which were then set up in two glass beakers containing tap-water, so that the roots of the seedlings just touched the surface of the water. One beaker was rotated clockwise about a vertical axis at one revolution a day, while the other was kept stationary. After 2 days, the length of each seedling shoot was measured to the nearest millimetre. The experiment was replicated fifteen times. The results, summarized in Table 2, show that shoots of rotated and stationary plants attained the same mean length. In individual replicates, the mean percentage difference between the length of rotated and stationary shoots ranged from −6·5 per cent to +10·0 per cent; but in no case was this difference statistically significant. From these results, and those for the preceding experiment, it is apparent that the extension growths of the root and shoot of the seedling of the oat variety used were not appreciably affected by daily rotation about a vertical axis in either direction.

Table 1. Effect of Rotation around a Vertical Axis at 1 Rev. a Day on Root and Shoot Extension Growth in *Avena* Seedlings

Table 2. Effect of Clockwise Rotation around a Vertical Axis at 1 Rev a Day on Shoot Extension Growth in *Avena* Seedlings
Results for 15 replicates

	Mean shoot length (mm)	Mean difference (%)	Total No. shoots per treatment
Stationary	39·7	−0·2	423
Rotated	39·6		435

While these negative results do not rule out the possibility that, under some environmental conditions, cyclamen and *Avena* plants may respond to slow rotation about a vertical axis, it can be concluded that the responses in question, if they exist, are not readily reproducible in the same way as, for example, are responses to darkness and temperature.

It is pleasing to see a renewal of interest in plant responses to specific rotations. Unfortunately Dr. Palmer's experiments with *Avena* are not strictly comparable with mine of 1960 in at least two features, that of the variety of oat used and in his choice of a 3-day period. I understand that the variety 'Milford' is now unobtainable, but I would mention that with it I was able to experiment with rotating seedlings in a null (magnetic) field, with negative response, that is, the direction of rotation did not affect the growth of shoots; a similar result was obtained with strong magnetic fields.

I would suggest that it might be worth while to carry out experiments with rotations in weak magnetic fields and that this might lead to some explanation of the phenomenon.

Mutants of *Puccinia graminis avenae* induced by Ethyl Methane Sulphonate

Spontaneous mutations affecting uredospore colour in cereal rusts have been observed by several investigators. The mode of inheritance of the mutant colours in the wheat stem rust fungus *Puccinia graminis tritici* E. and H. and oat stem rust fungus *P. graminis avenae* E. and H. has been shown to follow a simple Mendelian pattern[1,2] and such mutants serve as particularly useful markers in investigations of the role of asexual recombination in this group of fungi. In an attempt to produce uredospore

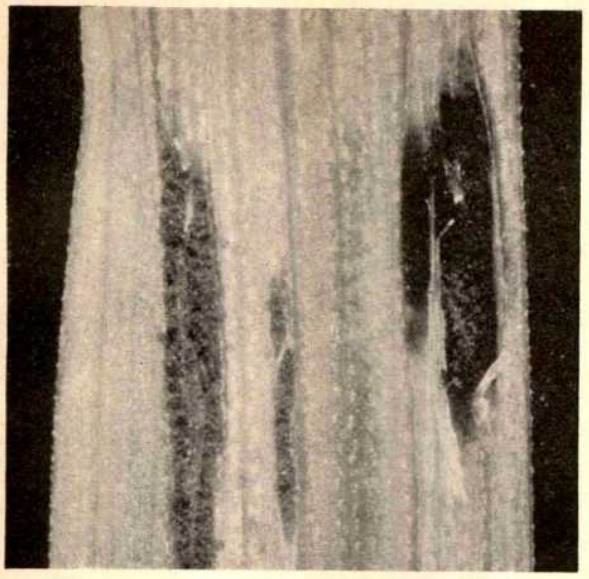

Fig. 1. Uredosori of normal oat stem rust (left) and teleutosori of short-cycle oat stem rust (right) 14 days after inoculation of uredospores on Algerian primary seedling leaf (× 12)

colour mutants in the oat stem rust organism for this purpose, the mutagenic effect of the alkylating agent ethyl methane sulphonate (EMS) was investigated following its success in this respect in such widely diverse organisms as bacteriophage[4] and barley[5].

Freshly collected uredospores of race 12[6] were treated with $0{\cdot}5 \times 10^{-2}$ M, $1{\cdot}0 \times 10^{-2}$ M, $1{\cdot}25 \times 10^{-2}$ M and $1{\cdot}5 \times 10^{-2}$ M solutions of EMS for 2 h with repeated shaking. The spores were then filtered from the solutions, washed several times, and those from each of the four groups were used immediately to inoculate the primary leaf of approximately 400 seedlings of 'Algerian', a variety of oats susceptible to race 12. Samples were retained to assess the effect of the treatments on spore germination.

Germination capacity was determined on 2 per cent non-nutrient agar at 20° C. Untreated spores showed 71 per cent germination; in the case of treated spores germination percentages were reduced from 27 following exposure to $0{\cdot}5 \times 10^{-2}$ EMS to 11 after treatment with $1{\cdot}5 \times 10^{-2}$ EMS.

Two distinctive colour variants were observed among the uredosori following the initial treatment with $1{\cdot}0 \times 10^{-2}$ M EMS. When compared with colour charts in Ridgeway's *Color Standards and Color Nomenclature*[7] the aggregated spores approached most closely 'Mars Yellow' (Plate III) and 'Ochraceous Orange' (Plate XV), and will here be referred to as yellow and orange, respectively. Comparatively, the reddish-brown spores of normal colour were best described as 'Amber Brown' (Plate III). Both mutants were characterized by delayed pustule formation, the uredosori rupturing the epidermis and developing 3–4 days later than the normal colour type. In repeated sub-cultures both mutant types have maintained their distinctive colours and shown delayed pustule development.

Recurrent treatment was then practised, apparently normal uredospores being repeatedly collected after each successive treatment and exposed to the same initial concentration of EMS. Following the fourth treatment with $1{\cdot}5 \times 10^{-2}$ M EMS a third mutant uredosorus, again appearing later than the normal type, was observed in which the massed spores most closely approximated 'Wood Brown' (Plate XL) in Ridgway's nomenclature. This mutant, which will here be referred to as grey-brown, has maintained its characteristics in repeated sub-cultures on the host plant. A control to the various treatments failed to produce any apparent uredospore colour variants.

Normal uredospores contained pigment in both the wall and cytoplasm. The orange mutant lacked pigment in the uredospore wall and that of the cytoplasm was intensely aggregated in the centre of the spore. In some instances macroscopically apparently normal coloured spores appeared in certain uredosori associated with this mutant type. Sub-cultures from mixed pustules with considerable development of reddish-brown areas produced exclusively orange pustules, at least when initially formed. Microscopically these normal coloured uredospores showed some pigment development in the wall, apparently associated with ageing of the spores under certain conditions. However, the characteristic central aggregation of the cytoplasmic pigment component was still exhibited. The yellow mutant lacked colour in the uredospore wall, while in the case of the grey-brown variant no pigment was visible in the cytoplasm. These descriptions agree in general with those of Newton, Johnson and Brown[1] for uredospore colour variants in *P. graminis tritici*.

Two mutant pustules characterized by rapid teleutospore formation were observed following the initial treatment with $1{\cdot}5 \times 10^{-2}$ EMS. In these instances teleutospores appeared in the uredosori 4–5 days after the rupture of the epidermis, and development progressed rapidly from the edge of the pustule towards the centre (Fig. 1). Uredospores were immediately taken from the centre of both pustules and inoculated on to seedlings of 'Algerian'. The characteristic rapid teleutospore formation has been observed in each subsequent generation of sub-culturing and these mutants have been difficult to maintain by uredospore transference on this account. Teleutospore formation was accelerated by increased temperature, and at approximately 27° C daylight temperature frequently no macroscopic formation of uredospores was observed, the pustules appearing immediately as teleutosori. By contrast, normal strains of the fungus do not form teleutosori on leaves under glasshouse conditions and teleutosori are usually restricted in the field to stems of mature plants. The advantages of mutations of this type, which may be designated as short-cycle rusts, in genetic studies involving the sexual stage on the alternate host, the barberry, is obvious. If mutations of this type can be simulated in rusts in general by alkylating agents with the same facility as in the present instance, genetic analyses of this group of fungi will be greatly expedited.

No change in pathogenicity was apparent with any of the mutant characteristics described, the reactions typical of race 12 being maintained on the differential set of varieties in each case. The variety 'Richland' gave a resistant reaction to this race with '1' reaction-type pustules on the conventional system for reaction-type designations[8]. The mutants with rapid teleutospore formation exhibited small teleutosori typical of the small '1' reaction-type uredosorus with no appearance of uredospores in the pustules.

Colour mutants in *P. graminis* have been found to be recessive[1,2]. The mutations of this type described here are at present being analysed genetically, but it is presumed that they have a similar genetical basis. The uredospores are diploid being dicaryotic with haploid nuclei. EMS was apparently an extremely efficient mutagenic agent in the present tests especially as there is no evidence to indicate that the strain of rust used was initially heterozygous at the appropriate loci.

Calcium Requirements of Higher Plants

The Hoagland nutrient solution for growing plants calls for the use of 0·004 or 0·005 M calcium and 0·002 M magnesium[1]. Plants grown in such solutions contain about the same amount of calcium as plants grown in soil. In the present investigation corn and tobacco plants have been grown with calcium levels 1/50 or less than that of Hoagland solutions. To accomplish this it was necessary to ensure that the copper level of the solutions was 200 p.p.b. or less, that unchelated iron was less than 0·5 p.p.m., that manganese was 0·5 p.p.m. or less, that zinc was 0·1 p.p.m. or less, and that magnesium was 5×10^{-4} M or less. There were some variations due to plant species.

Calcium is required by some algae and other micro-organisms in micro-nutrient quantities only[2] and perhaps also for a gymnosperm[3]. Higher plants seemingly require relatively large quantities of it. The concentration of it in leaves of higher plants generally ranges from 0·2 to more than 5 per cent of dry weight[4]. There are a large number of experiments which indicate that higher plants benefit from the high levels of calcium which they contain.

Calcium-levels in leaves of from 200 to 800 p.p.m. of dry weight appear to be sufficient under some conditions (Tables 1 and 2). The magnesium-level simultaneously must be relatively low since high magnesium-levels can be very toxic under low calcium-levels[5]. The calcium and magnesium assays were made from wet digested samples with an atomic absorption flame spectrophotometer.

There is some indication also that with proper balance the magnesium requirement is also in the same magnitude as that of calcium. The lower limit of sufficient magnesium cannot be less than its need in chlorophyll. This amounts to a need of about 0·03 per cent magnesium on the dry weight basis. The co-factor requirements for magnesium in enzymatic reactions add roughly an additional 0·03 per cent to the magnesium requirement. This is based on a concentration of about 1 mM in the plant liquid. The total magnesium requirement, therefore, would be about 600 p.p.m. of dry weight. Critical magnesium levels for plants generally have been reported as from 0·2 to 0·3 per cent of dry weight for different plant species. This is around three times the postulated level. The difference has never been reconciled and may be related to the calcium-levels, which are usually high. The data in Table 1 indicate that the need for magnesium in tobacco may be from 800 to 1,200 p.p.m. of dry weight.

The plants grown without added calcium as described in Table 1 did have some indications of calcium deficiency as indicated by yields and by appearance of growing tips. When neither calcium nor magnesium was supplied the new leaves had an unnatural curl. The new leaves of these plants contained 80–90 p.p.m. calcium on the dry weight basis, which under the conditions of the experiment was slightly too low for maximum yield. Although these plants were decreased in yields by about 30 per cent they looked reasonably healthy. The relatively high calcium-levels of the old leaves on the plants was due to a pretreatment complete nutrient solution together with no retranslocation of calcium from old to new leaves.

Table 1. Yields and Calcium and Magnesium Contents of Tobacco Plants grown in Complete Nutrient Solutions except for Calcium and Magnesium

Plant part	Differential treatments		
	No calcium, no magnesium	5 mM calcium, no magnesium	5 mM calcium, 4 mM magnesium
	Dry weight/plant (g)		
Shoot	11·6	17·3	15·4
Root	1·7	2·1	2·3
Whole plant	13·3	19·4	17·7
	Calcium (percentage of dry weight)		
New leaves	0·009	0·63	0·44
New mature leaves	0·008	0·57	0·39
Remainder of shoot	0·41	1·26	1·14
Root	0·048	0·44	0·23
	Magnesium (percentage of dry weight)		
New leaves	0·08	0·08	0·22
New mature leaves	0·03	0·03	0·17
Remainder of shoot	0·12	0·10	0·28
Root	0·22	0·12	0·44

Table 2. Yields and Calcium Contents of Corn and Tobacco grown in Nutrient Solutions at Two Calcium Levels

Calcium (p.p.m.)	Yield (g)	Leaf calcium (percentage of dry weight)
		Corn
2	5·1	0·011
5	4·8	0·020
		Tobacco
2	18·6	0·08
5	18·6	0·10

The plant species have been grown in a number of nutrient solution cultures to test their need for calcium. They grew well at the low calcium-levels (Table 2). These data were obtained with 1 mM magnesium, 20 p.p.b. copper and chelated iron and indicate that from 100 to 200 p.p.m. calcium in corn leaves on the dry weight basis is sufficient and that not more than 800 is sufficient for tobacco.

There is considerable evidence that plants do not require all the calcium they ordinarily contain and the present investigation indicates that published critical levels do not reflect the direct need of plants for calcium. They reflect the ability of calcium to prevent injury from excesses of magnesium, copper, iron, manganese, zinc, and possibly other ions.

Corn and tobacco plants grew well in nutrient solutions at calcium-levels lower than 1/50 of that of Hoagland solution provided that levels of copper, iron, manganese, zinc and magnesium were in proper balance. The implication is that beyond ameliorating toxicities of other ions, the role of calcium in higher plants is that, or nearly that, of a micro-nutrient.

Introduction and Exchange of Coconut Planting Material

The presence of cadang-cadang, lethal yellowing, red ring and other serious diseases in important coconut growing areas, coupled with an awareness of genetic differences in palms in different parts of the world, has stimulated an interest in disease resistance testing. The occurrence of known resistance to lethal yellowing disease in Jamaica has served to emphasize the possibilities.

Pollen introductions greatly speed up the production and testing of hybrids between local and exotic material, but do not eliminate the necessity for seed importations[1]. Coconut seed often has low viability following shipment by sea, and the need for research on collection and dispatch has recently been emphasized[2]. Preparatory to survey and collection of coconut planting material[3], air freight and fumigation tests were therefore undertaken.

Short distance air freight (return trip to Miami from Jamaica) did not affect seed germination, and good germination was also obtained with samples introduced from Wallis Island and with seed exported to West Africa.

Germination of seed nuts with the husk removed is a standard procedure in Jamaica for the production of coconut seedlings for investigations of disease transmission. In a long-distance air freight experiment (Jamaica–England–Jamaica; at high altitude) equal

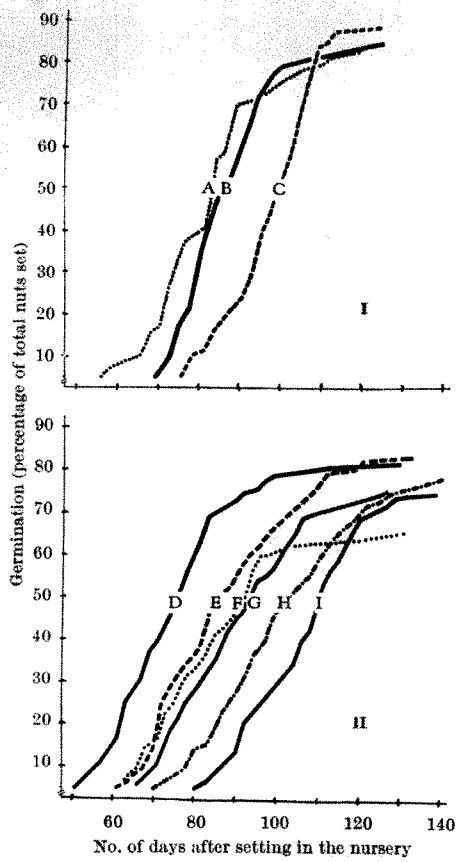

Fig. 1. Germination rates of coconut seed nuts introduced to Jamaica by air freight. I, Completely husked seed nuts; II, partially husked nuts and one sample (*H*) not husked. *A*, Fiji (local talls); *B*, W. Samoa; *C*, Rangiroa (red fruited dwarf); *D*, F.M.S., Solomons; *E*, Bougainville; *F*, Markham Valley, New Guinea; *G*, Karkar Island, New Guinea; *H*, Tahiti; *I*, Rennell Island. Curves for introductions from Fiji ('Niu Leka' dwarfs), Solomon Islands (local talls) and New Hebrides resembled *B*, *D* and *F*, respectively

numbers of husked and unhusked coconuts, packed in hessian bags, were placed both in the forward and rear holds of the aircraft: controls were retained in the laboratory. Results are given in Table 1.

Germination of nuts carried in the forward hold and complete nuts carried in the rear hold was satisfactory. Results for husked nuts carried in the rear hold may be inconclusive as, on this occasion, controls also had poor germination. Germination of nuts with the husk removed normally exceeds 70 per cent and 90 per cent, respectively, for 'Malayan Dwarfs' (as used in the present experiment) and 'Jamaica Talls'. There was no apparent damage during shipment; some breakages in a subsequent consignment served to emphasize the need for adequate packing of 'depericarped' nuts. In the latter shipment 77 per cent of the undamaged nuts germinated.

Since fumigation of seed is often essential, the effect of two commonly used fumigants was tested. Germination and early growth of husked and unhusked seed treated with hydrogen cyanide (1 oz. and 0·5 oz. potassium cyanide per 300 ft. respectively, for 1 h) and methyl bromide (1 lb. per 1,000 ft. for 2 h) were at least comparable to those of untreated controls.

The preliminary trials indicated that, with certain precautions, introductions could be safely made by air freight. With later shipments, mainly from different Pacific Islands, over-dried and immature seed nuts were avoided, and only those with drying husk, and calyx still retaining the 'living' colour, were dispatched. Most seed was partly husked, leaving a thin (1 cm) protecting layer. Husking was complete only when packing in boxes was possible. Insecticide dusting and fumigation conformed with individual territory regulations and all samples were carried in the forward hold of the aircraft. At destination, seed with incomplete husk was planted in a coir and soil mixture contained in bamboo baskets placed in full sunlight. In a preliminary trial, 1 in. depth of medium above each seed prevented nut cracking due to exposure. Most seed nuts were placed in a horizontal position; only the Rennell introductions had the germ pore uppermost. Although there is less mechanical hindrance to growth of seedlings planted in baskets, using the latter method, rate and final percentage germination may be slower[4].

Table 1. Percentage Germination of Coconut Seed after Long-distance Air Freight

	Forward hold	Rear hold	Control
Complete coconuts	70	90	75
Husk removed	81	25	33

Germination rates for the introduced samples are given in Fig. 1. Nut maturity and germination conditions were similar and there are indications of different germination patterns for seed of different origins. However, sample sizes were relatively small (90–200 nuts). Most seed germinated rapidly, unlike that of 'Jamaica Talls'[5], and final percentages were satisfactory. With quick germinating seed it is particularly important to avoid over-maturity and delays in shipping.

The coconut husk protects against desiccation and mechanical injury and, if the husk is removed, careful handling at all stages is essential. Transplanting of seedlings complete with baskets is advisable. Complete or partial husking reduces cost of transport (by 30–50 per cent) but freight costs are relatively very small in view of the possible benefits for areas with serious disease problems. A recent estimate for cadang-cadang, which threatens loss of livelihood for one-third of the population in the Philippines, put cash losses at more than 300 million dollars[6].

The survey and introduction of coconut planting material were financed by the British Department of Technical Co-operation. We thank Dr. G. P. Chapman and Dr. G. H. Sidrak, of the University of the West Indies, for their assistance.

Gibberellin-induced Anther and Pollen Development in a Stamen-less Tomato Mutant

Heslop-Harrison[1] has pointed out that in most investigations flower primordia differentiation has been considered synonymous with flowering as a single indivisible process. Observations on the differentiation and development of individual floral parts (sepals, petals, stamens, pistils) in hermaphroditic flowers thus offer a unique approach in the study of flowering. Certain tomato mutants lacking essential floral parts provide excellent source material for such investigations. This report directs attention to the effects of gibberellin A_3 (GA_3) on anther and pollen development in an otherwise stamen-less tomato mutant[2].

Rooted stem cuttings of the stamen-less mutant were initially exposed to 25 p.p.m. of GA_3 and other chemical stimuli in aerated solution culture root media[3]. Anthers developed in the flowers of plants exposed to GA_3 within 3–4 weeks. Viable pollen was also produced in these GA_3-induced anthers. Progeny grown from seed obtained by

selfing gave 100 per cent stamen-less plants. Such plants must otherwise be propagated from seed with a segregating population of one stamen-less to three normal[4].

In a second and more detailed experiment, uniformly rooted cuttings of the stamen-less tomato were exposed to 0, 10^{-5}, 10^{-4}, or 3×10^{-4} M GA_3 in solution culture root media, and to a 0, 10^{-5}, 10^{-4} or 10^{-3} M GA_3 foliar spray application in all combinations. All solutions constituting the root medium were renewed to the designated GA_3 concentrations at 6-day intervals. After 18 days of continuous exposure to the various gibberellin-levels in the root media the containers were rinsed with water and filled with half-strength Hoagland nutrient solution only.

Concentrations of 10^{-4} or 3×10^{-4} M in the solution culture root medium resulted in essentially all flowers having fully developed anthers (Table 1). Microscopic observations of acetocarmine preparations revealed that these anthers contained normal pollen. The induced anthers, however, did not form normal stamen cones around the style and stigma, but were curled and twisted (Fig. 1). Curling of anthers was most prominent at the highest (3×10^{-4} M) GA_3 concentration. Flower clusters which appeared on plants 3–4 weeks after termination of the GA_3 treatments showed no anther development. Furthermore, flower buds which were visible at the initiation of the GA_3 treatments were not affected. Anther development thus appeared a function of the presence of gibberellin during the flower-forming process.

Table 1. Anther and Pollen Formation in a Stamen-less Tomato induced by Gibberellin A_3 in the Solution Culture Root Media

Concentration of gibberellin A_3 (molar)	Inflorescence 1	2	3	4	5
	(Per cent flowers with anthers and pollen) (Average of 24 plants)				
0	0	0	0	0	0
10^{-5}	0	0	5	7	0
10^{-4}	0	0	98	100	0
3×10^{-4}	0	0	100	100	0

Further investigations revealed that 2-chloroethyl-trimethylammonium chloride (CCC), which inhibits fungal gibberellin synthesis[5], inhibits pollen formation in gibberellin-induced anthers. Vegetatively propagated stamen-less tomato mutants were exposed to all possible combinations of GA_3 at 0 and 10^{-4} M and CCC at 0, 10^{-5} and 10^{-4} M in the solution culture root media. Abnormal pollen was observed in the anthers of plants exposed to a combination of CCC at 10^{-5} M and GA_3 at 10^{-4} M. No pollen developed in the anthers of flowers from plants exposed to 10^{-4} M CCC plus 10^{-4} M GA_3.

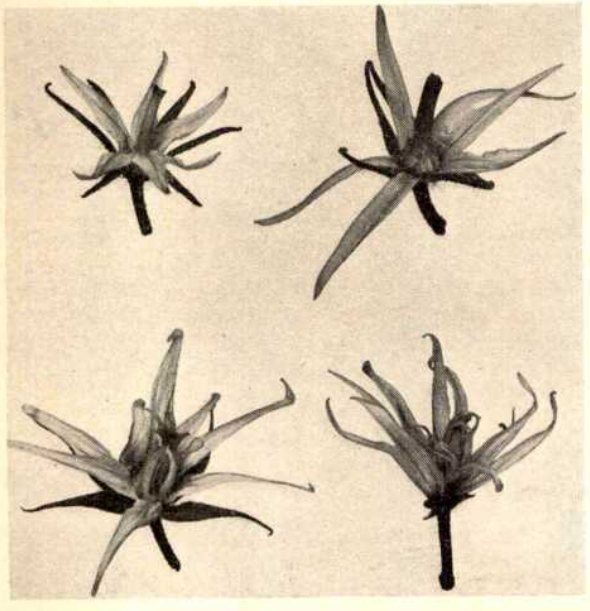

Fig. 1. Effect of various concentrations of gibberellin A_3 applied through the solution culture root medium on the development of stamens in the flowers of a stamen-less (*sls*) tomato mutant. From left to right and top to bottom: 0 (control), 10^{-5}, 10^{-4}, and 3×10^{-4} M

Several reports have suggested that gibberellin and auxin may play a determinative part in the development of male and female gametophytes in monoecious and gynoecious plants[6–10]. The present investigations suggest that gibberellin or gibberellin-like substances are necessary for the development of male gametophytes in the tomato, and that this influence is exerted after flower initiation.

We thank Dr. T. O. Graham, Department of Horticulture, Ontario Agricultural College, Guelph, Ontario, for providing seed, and Sherrill Kocan for assistance in recording data. Gibberellin consisted of potassium gibberellate and was supplied by Merck and Co., Rahway, N.J.

Comparison of the Spectrum of Amino-acids in the Bleeding Sap of Wheat Maize and Rice

A number of compounds are known to be translocated in the transpiration stream. These include the building blocks needed for protein synthesis and also compounds postulated to play a part in the regulation of protein synthesis in leaves[1,2]. In the present investigation the spectrum of amino-acids translocated in the bleeding sap of three plant species was compared to provide data on the species specificity of the pattern observed.

Wheat variety 'Besostaia 1', maize variety 'Szegedi sarga lofogu' and rice variety 'Dubovskij 129' were included in the experiments. Bleeding sap was collected at the flowering stage during the night. The sterile sap was subjected to one- or two-dimensional paper chromatography (ascending technique, filter paper Whatman No. 1, 2 : 1 : 1 mixture of butanol–acetic acid–water or a 4 : 1 mixture of phenol–water). Hydrolysis with hydrochloric acid was carried out for 24 h at 105° C. Amino-acids supplied by British Drug Houses, Ltd., served as standards.

It can be seen from Fig. 1 that 10–14 amino-acids could be detected in the bleeding sap of cereals. Glutamine and asparagine were the major components in the bleeding sap of all three plants. In contrast to other authors[4,5] reporting on the presence of arginine or alanine in the bleeding sap as major components we have found remarkable quantities of ornithine to be present. Hydrolysis of the exudate resulted in the disappearance of the amides and in the accumulation of the corresponding amino-acids. The amount of ornithine remained unchanged.

As no significant amounts of arginine and citrulline could be detected in the bleeding saps it seems probable that the ornithine observed is not derived from the carbamide cycle. Ornithine present in significant amounts might either represent a translocation amino-acid or a regulatory substance supplied by the root. This suggestion is supported by the finding that no significant amounts of ornithine are present in the shoot.

It is also important to emphasize that of the bleeding saps tested, that of the rice plant exhibited the richest

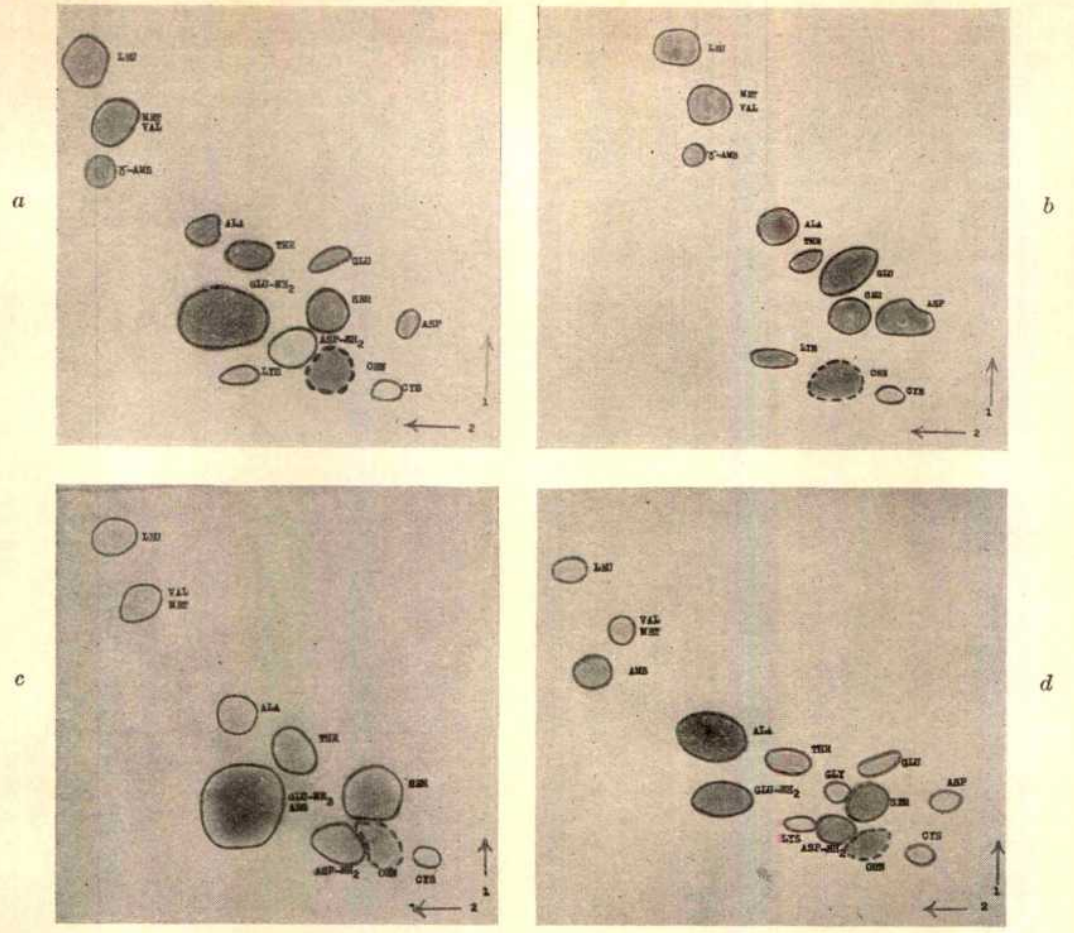

Fig. 1. Amino-acids in: *a*, bleeding sap of wheat; *b*, bleeding sap of wheat after hydrolysis; *c*, bleeding sap of maize; *d*, bleeding sap of rice

amino-acid spectrum. This is probably due to the fact that rice is grown under irrigated conditions and in the flooded soil nitrogen occurs mainly in the reduced form. Ammonium–nitrogen is more readily transformed into organic form than nitrate–nitrogen, which has first to be reduced[5].

The high ornithine of all the bleeding saps investigated might suggest a general role for ornithine as a transport amino-acid.

MICROBIOLOGY

Possible Importance of Transfer Factors in Bacterial Evolution

Bacterial transfer factors are virus-like agents which mediate the transmission of genetic characters by conjugation in the Enterobacteriaceae. The first to be discovered was the *F* or 'sex' factor of *Escherichia coli* K12 (ref. 1), and for some time this was the only one to be investigated. The demonstration of the transmissibility of colicinogeny[2], and the discovery of transferable drug resistance[3–5], revealed the existence of a multiplicity of transfer factors. Recent work[6–8] suggests that such factors are basically independent of the genetic characters they carry and that they are widely distributed in the Enterobacteriaceae. It is probable that drug resistance and colicinogeny are only two of a range of characters they can transfer.

The transfer factors lack an independent invasion mechanism. They are thus dependent on their host cells to provide the apparatus for their transmission, although the production of this apparatus is probably coded by the transfer factors themselves. The mechanism of transmission is highly efficient, and often leads to infection of almost 100 per cent of cells of recipient strains.

Some bacteria carry genetic determinants which are apparently cytoplasmic in location. The determinants so far subjected to intensive investigation are those concerned with drug resistance and colicinogeny, but there seems to be no reason for doubting that other bacterial characters have the possibility of cytoplasmic determination. The genetic fragments responsible for drug resistance have been designated *R*-determinants. The origin of these determinants is unknown; they may have been initially chromosomal, but the possibility of an intrinsically cytoplasmic origin must also be considered.

Because the *F* factor seems to be concerned mainly with chromosomal transfer, a process which may be relatively unimportant in the distribution of genetic characters in the Enterobacteriaceae, the following discussion is concerned mainly with transfer factors other than *F*.

When a transfer factor infects a cell containing an *R*-determinant, the two elements 'combine' to form a transferable resistance factor (*R*-factor) which can be transmitted by conjugation to other bacterial cells. This transfer occurs within the strain originally containing only the *R*-determinant, and also to strains initially carrying neither the *R*-determinant nor the transfer factor. The *R*-factor also spreads to the strain which originally donated the

transfer factor, so that this strain, too, acquires an advantage in an environment in which the new character is needed for survival.

The transfer factor may be lost at some stage during the spread of an *R*-factor[6]. The resulting organism retains the *R*-determinant which it can transmit to its lineal descendants only and which appears to be stable. Superficially, these organisms resemble drug-resistant mutants.

The transfer factors have a very wide host range. For example, they may be transmitted, together with the resistance determinants they carry, and presumably with other genetic determinants, to the following 'genera' of Gram-negative bacilli: *Escherichia, Salmonella, Shigella, Proteus, Serratia, Pasteurella, Vibrio*, and others. The full range of characters for which the transfer factors can act as vectors is not yet known, but it may prove to be extensive. The same transfer factor will transfer different characters and the same character may be carried by different transfer factors.

The observations presented here suggest that the transfer factors may have more evolutionary importance in the bacterial systems in which they operate than has been hitherto imagined. Although devoid of the property of extra-cellular invasion, they have an immense ecological advantage because of their high communicability and wide host range. They can carry genetic determinants which may ultimately prove to be numerous. By this mechanism these determinants may be widely distributed among different species or genera of Gram-negative bacilli, so that determinants in a given strain may have originated in a bacterial species normally regarded as belonging to a different genus. Whether such genetic determinants can become integrated into the chromosomes of their new carrier cells is not yet known. If they can, it may be supposed that, once integrated, they are indistinguishable in origin from other chromosomal characters and are localizable on the bacterial linkage map. But even if they remain cytoplasmic in location they are stable cellular components. Whether they enter the chromosome or remain cytoplasmic, therefore, they become part of the genome of their host cells.

Extensive exchange of characters between the Gram-negative bacilli need not be expected to lead to genetic uniformity in the different host species, except in relation to the individual characters concerned. On the contrary, it may encourage diversification, because in each case the effect of a new character has to be assessed through its summation with the bacterial genome as it existed up to the time of acquisition of the new character, and the ultimate effect of the now modified genome on the ecology of the recipient organism.

I thought it worth while to voice these speculations because if the long-term activity of transfer factors has influenced bacterial evolution, the evolutionary time-scale may have been telescoped into a shorter span than that envisaged purely in terms of the selection of mutants with survival advantages. The obvious question that arises is whether efficient mechanisms of genetic distribution such as those I have discussed exist only in the Enterobacteriaceae, or indeed whether they are limited to the bacteria. If they operate in other forms of life, some re-thinking may be called for in relation to evolution in other fields of biology.

Correlation of Temperature-dependent Water Properties and the Growth of Bacteria

In recent years there has been some evidence to suggest that biological activity may be affected by water structure[1,2]. The premise of the above work was that water undergoes subtle structural changes at specific temperatures[3,4] and, if biological growth is affected by water structure, growth should be affected at these temperatures. Since the effect of water structure on biological activity has not been substantiated, an investigation of the effect of temperature on bacterial growth was undertaken.

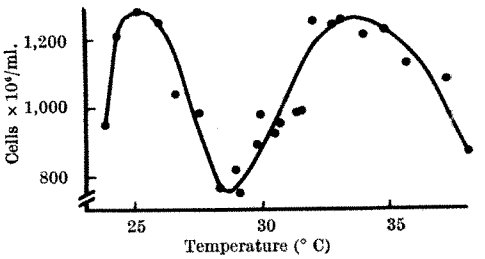

Fig. 1. Number of cells of *Streptococcus faecalis* at different temperatures

Using a polytemperature thermostat, similar to that described elsewhere[2], cultures of *Streptococcus faecalis* were simultaneously grown in broth culture at nineteen temperatures ranging from 20° to 40° C. The culture tubes were prepared and placed in the incubator at least 8 h prior to inoculation so that temperature equilibrium within the medium would be reached. Inoculum consisted of a loop of cells from a 24-h broth culture of the organism. Growth was stopped after a 20-h incubation period by placing the culture tubes in 50° C water. Bacterial multiplication was determined by direct cell counts in a haemocytometer.

Typical results are shown in Fig. 1. Near 30° C there is a marked reduction in number of cells. The temperature of reduced cell multiplication corresponds to a temperature at which a change in water structure takes place. These data support the postulate that biological activity is affected by water structure. This work is being extended to other bacteria and temperatures.

Staphylococcus aureus Strains in the '52, 52A, 80, 81 Complex'

The phage-typing pattern of a strain of *Staphylococcus aureus* is believed to be determined by two factors: the 'basic' sensitivity of the strain to lysis by the typing phages, modified by interference exerted by the prophage or prophages it carries. The specificity of this interference may be narrow, and prevent lysis only by the phage carried by the strain and by closely related phages, or it may be very broad. Sometimes a single prophage will block the sensitivity to a number of apparently unrelated phages and have a profound effect on the phage-typing pattern[1,2].

Under natural conditions the typing pattern of a strain may be changed by lysogenization, and this may lead to difficulties in the interpretation of long-term epidemiological investigations. It has proved possible, however,

to define by *in vitro* studies some of the changes in typing pattern which might be expected to occur in the field, and these correspond very well with the observed changes in strains endemic in hospitals[3]. The most widely studied group of strains is the '52, 52*A*, 80, 81 complex', which comprises strains with one of the following phage-typing patterns: 80, 81, 80/81, 52/52*A*/80, and 52/52*A*/80/81. The relation between these strains has been clarified by investigations carried out in a number of laboratories[4–10] (see Fig. 1).

(1) Strains of phage-type 80/81 are lysogenic for a completely defective prophage, designated 80′. Sensitivity to the two typing phages, 52 and 52*A*, is blocked almost completely in strains carrying this defective phage[9]. The typing pattern of such strains changes from 80/81 to 52/52*A*/80/81 when prophage 80′ is lost spontaneously[4].

(2) Prophage 80′ may also be lost as a result of prophage substitution during lysogenization with a number of phages carried by various members of the '52, 52*A*, 80, 81 complex'.

(3) Some of these phages have no direct effect on the typing pattern, but the loss of prophage 80′ results in a change of typing pattern from 80/81 to 52/52*A*/80/81 (class 1 phages)[9].

(4) Others (class 2 phages) block the sensitivity to phage 81 on lysogenization. They may also occasionally substitute for prophage 80′. When this substitution occurs the change is from 80/81 to 52/52*A*/80; a change from 80/81 to 80 occurs when substitution does not occur and the strain becomes doubly lysogenic for prophage 80′ and the class 2 phage[5,11].

(5) Members of another group of phages block sensitivity to the three phages 52, 52*A* and 80, and lysogenization of an organism with the typing pattern 80/81 or 52/52*A*/80/81 with one of them causes the pattern to become 81 (class 3 phages)[4,11].

(6) Still other phages (class 4) block the sensitivity to all four phages in the complex and thus change previously 'typable' strains to 'untypable' ones[11,12].

Rountree[4] noted that certain members of phage-type 80/81 carried, in addition to the defective prophage 80′, a fully active phage belonging to serological group *F*. This phage did not seem to play any part in the changes already described, since it was present in all members of the complex that had been investigated. It appeared, therefore, that the 'basic' phage-typing pattern of strains in the complex was 52/52*A*/80/81.

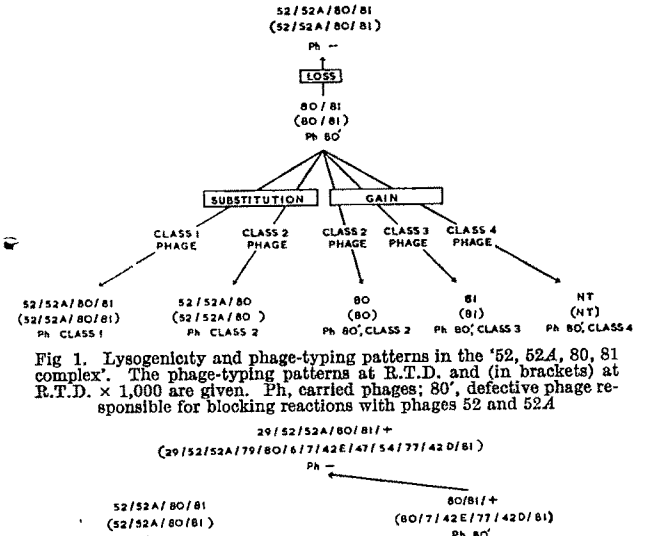

Fig 1. Lysogenicity and phage-typing patterns in the '52, 52*A*, 80, 81 complex'. The phage-typing patterns at R.T.D. and (in brackets) at R.T.D. × 1,000 are given. Ph, carried phages; 80′, defective phage responsible for blocking reactions with phages 52 and 52*A*

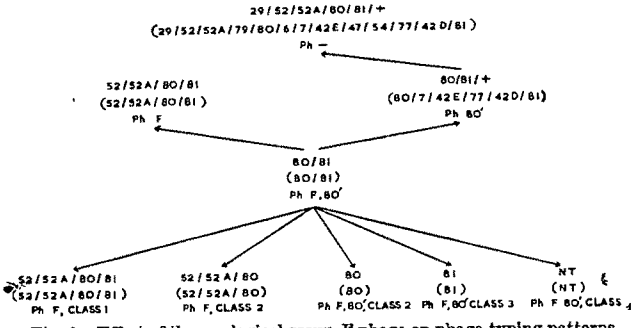

Fig. 2. Effect of the serological group *F* phage on phage-typing patterns in the '52, 52*A*, 80, 81 complex'. The phage-typing patterns at R.T.D. and (in brackets) at R.T.D. × 1,000 are given

Recently, however, Winkler and his colleagues[13] reported that staphylococci of phage-type 80/81 showed a considerable broadening of their typing pattern when they lost the group *F* phage, and were now sensitive to phages 7, 42*E*, 77 and 42*D*. This was confirmed for *P.S.* 80, the propagating strain for phage 80, which has the phage-typing pattern 80/81. This culture was screened for mutants that had lost the group *F* phage spontaneously, using strain 57 as indicator strain for the phage[13]. Having obtained this mutant, a second experiment was carried out to detect a mutant that had also lost the defective prophage 80′. Such a strain has now been obtained, and has the following typing pattern:

at R.T.D. (routine test dilution) : 29/52/52*A*/80/81/+ (weak reactions with 7, 42*E*, 77 and 42*D*)

at R.T.D. × 1,000 : 29/52/52*A*/79/80/6/7/42*E*/47/54/77/42*D*/81

It is, of course, impossible to be certain that this strain is completely non-lysogenic and represents the true 'basic pattern' of members of the '52, 52*A*, 80, 81 complex'. It is noteworthy, however, that such a staphylococcus, which would be classified as a member of phage group I–III, should be the precursor of a series of strains which belong to phage-group I; it might equally be the precursor of typical group III strains if it was lysogenized by phages able to block reactions with the group I phages.

The peculiar lysogenic state of members of phage-type 80/81 from widely separated parts of the world also deserves comment. All are doubly lysogenic for a particular serological group *F* phage and for a completely defective phage of unknown serological group. It is unlikely, therefore, that such strains arose independently in a number of different countries, and more probable that the two lysogenizations occurred as separate events in a single organism which has since spread widely throughout the world.

The relation of the non-lysogenic precursor strain to the members of the '52, 52*A*, 80, 81 complex' is summarized in Fig. 2.

VIROLOGY

Possible Correlation between Virus Particle Size and Activity of Antiviral Agents

Some success has already been achieved in the chemotherapy of infections caused by the larger viruses, but compounds with an equal degree of activity against the

smaller viruses seem much more difficult to find. It is therefore natural to enquire whether there is any relationship between the size of virus particles and the activity of chemotherapeutic agents. As a working hypothesis one may adopt the postulates that (*a*) a compound is maximally efficient if 1 molecule can inhibit the maturation of 1 virus particle, and (*b*) that to obtain maximal activity each volume of the cytoplasm of the infected cell equivalent to the volume of a virus particle must contain 1 molecule of the compound. From these postulates the minimal inhibitory concentration of a maximally effective compound can be calculated. Thus, 1 molecule must be present in a volume of $\frac{4\pi r^3}{3}$, where r is the radius of the virus particle in mμ. In 1 l. there will be $\frac{3 \times 10^{24}}{4\pi r^3}$ molecules. Since there are $0{\cdot}606 \times 10^{24}$ molecules in a gram molecule, this represents a molarity of $(0{\cdot}808\pi r^3)^{-1}$, whence log molarity $= -0{\cdot}4045 - 3 \log r$.

This theoretical linear relationship between the logarithms of particle size and minimal inhibitory concentration has been plotted in Fig. 1, in which the particle diameter, as being a more familiar measurement, has been substituted for the radius.

Information is available in the literature on the activities of a number of compounds with antiviral activity, and the points corresponding to the minimal concentration causing complete inhibition and the particle diameter of the relevant virus have been inserted in Fig. 1. The compounds and viruses are: methisazone (1-methylisatin 3-thiosemicarbazone) and rabbitpox[1]; 5-fluoro-2′-deoxyuridine and vaccinia[2]; idoxuridine (5-iodo-2′-deoxyuridine) and herpes[3], vaccinia[4] and zoster[5]; *p*-fluorophenylalanine and vaccinia[6]; amantidine hydrochloride and influenza[7], and rubella[8]; 5-chloro-2-(α-hydroxybenzyl)benzimidazole and poliomyelitis[9]. None of these points lies below the line. The hypothesis is therefore not invalidated by any antiviral agent known at present, and with due reservations will be taken as valid for the purpose of further discussion.

The distance of a point from the line can be taken as a measure of the efficiency of the compound, which can be defined in numerical terms as the ratio of the theoretical and actual inhibitory concentrations expressed as a percentage. Thus, the efficiency of methisazone against rabbitpox and of 5-fluoro-2′-deoxyuridine against vaccinia is 15 per cent. Idoxuridine (0·55 per cent) and *p*-fluorophenylalanine (0·01 per cent) are much less efficient. The efficiency of idoxuridine against herpes is 4·6 per cent, and against zoster 0·005 per cent. The efficiency of amantidine hydrochloride against rubella and influenza

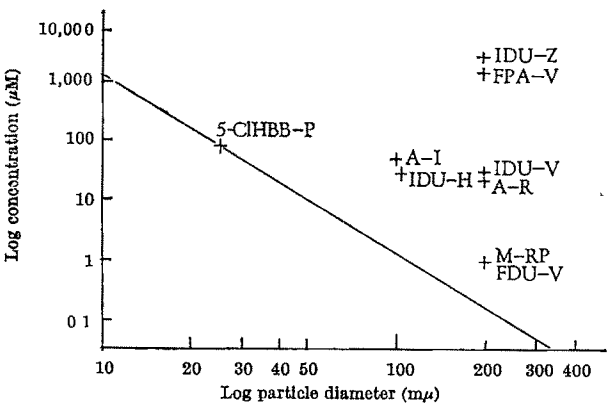

Fig. 1. Relationship between minimal effective concentration of an antiviral compound and virus particle diameter. The line represents the theoretical relationship for a maximally effective compound. The points represent the activities of known antiviral compounds against the relevant viruses. Abbreviations: 5-ClHBB, 5-chloro-2-(α-hydroxybenzyl)benzimidazole; A, amantidine hydrochloride; IDU, idoxuridine, FPA, *p*-fluorophenylalanine; M, methisazone, FDU, 5-fluoro-2′-deoxyuridine; P, poliomyelitis, I, influenza; H, herpes; Z, zoster, V, vaccinia; R, rubella, RP, rabbitpox

Table 1. Relation between Predicted Minimal Inhibitory Concentration of Antiviral Compound and Virus Particle Diameter

Virus	Diameter (mμ)	Minimal inhibitory concentration (mg/l.)	Equivalent adult dose (mg)
Varicella	200	0 03	2
Mumps	140	0·09	6
Measles	140	0 09	6
Rubella	~130	0·11	8
Respiratory syncytial	130	0 11	8
Influenza	~100	0 25	17
Cytomegalovirus	87	0 37	26
Adenovirus	80	0 38	27
Verruca	45	2 7	190
Rhinovirus	31	8·3	580
Coxsackie	28	11 3	790
Tick-borne encephalitis	25	15 8	1,100
ECHO	25	15 8	1,100
Foot-and-mouth disease	22 5	21·7	—
Infective hepatitis	15	73 3	5,100

is low (2·2 per cent and 2·5 per cent, respectively), and it should be possible to find much more active compounds. Against poliomyelitis, however, the efficiency of 5-chloro-2-(α-hydroxybenzyl)benzimidazole is 100 per cent, so that according to the hypothesis a search for more active compounds would be pointless.

The predicted minimal inhibitory concentrations for viruses for which there are as yet no effective antiviral agents are shown in Table 1. As the object of research into antiviral chemotherapy is to find compounds which can be of use in medical and veterinary practice, the concentrations have been transformed into doses in mg/l. (that is, mg/kg) for a compound with a standard molecular weight of 200, and also to the equivalent dose in grams for an adult weighing 70 kg. The dose indicated would provide a concentration in the infected tissue of the desired level only if the compound were perfectly absorbed, uniformly distributed, slowly metabolized and slowly excreted. These requirements will be fulfilled only rarely, and to allow for deficiencies in this respect the theoretical dose would have to be multiplied several-fold. For the viruses from varicella to verruca the revised dose would still be within reasonable limits, but it would follow that treatment or prophylaxis of the common cold would require repeated doses of the order of several grams, and treatment of infective hepatitis might not be practicable. These limitations could only be overcome by the discovery of compounds which had exceptionally favourable pharmacological characteristics, or which had a selective affinity for the infected tissues which would enable the requisite concentration to be obtained with lower doses. Compounds capable of acting against the smaller viruses would elude detection if their solubility in water was less than the predicted minimal inhibitory concentration, and it would seem reasonable to concentrate the search in this case on compounds with high solubility and low molecular weight.

AGRICULTURE

Occurrence of Sucrose in the Fruit of Some Species of *Lycopersicon*

Two sub-genera are recognized in the genus *Lycopersicon*[1,2]. In one of these the plants are annuals and bear fruits containing carotenoids and lycopene (*Eulycopersicon*). In the other the plants are perennials

with fruits pigmented with chlorophyll and anthocyanins (*Eriopersicon*). The composition of the fruit of the subgenus *Eulycopersicon*, which includes all tomato varieties in commercial production, has been studied extensively, but apart from investigations of their vitamin C and carotene contents[3,4] few data are available for fruit of *Eriopersicon*.

The free sugars of commercial varieties of tomato fruit are predominantly reducing sugars[5,6], the sucrose content rarely exceeding 0·1 per cent on a fresh weight basis[5]. Quantitative chromatographic investigations have shown that the reducing sugars consist almost entirely of glucose and fructose present in approximately equal amounts with, in general, a slight preponderance of the latter[7–11]. Sucrose, when found at all, is present in small amounts only[7,8,10]. Traces of other sugars have been detected, notably a ketoheptose[7], and raffinose, which has been reported in the fruit of an Indian wild variety[12].

Recent investigations of the composition of the expressed juices of the mature fruit of various species of *Lycopersicon* used as sources of genetic material by the Plant Breeding Department have been made at this Institute. Fruit of *Eriopersicon* species, although not unduly acid and having very low reducing-sugar contents, were characterized by abnormally high total solids contents. A preliminary examination by paper chromatography in several solvent mixtures explained this apparent anomaly by revealing, in addition to glucose and fructose, the presence of considerable quantities of a sugar indistinguishable from sucrose. Elution of this sugar from the paper followed by hydrolysis under mildly acid conditions or by incubation with invertase gave a solution containing two sugars which travelled on a paper chromatogram at the same rate as glucose and fructose respectively. Trace amounts of other, as yet unidentified, carbohydrates were also detected in the fruit of some species.

Quantitative determination of the individual sugars in 80 per cent ethanol extracts of the fruit of various species of *Lycopersicon* by paper chromatographic techniques outlined previously[10] gave the results shown in Table 1. Analyses for fruit of the variety 'Moneymaker' (*L. esculentum*) at two stages of ripeness are included in the table for comparison. Sucrose was determined by measuring the increases in glucose and fructose produced following incubation with invertase (B.D.H. concentrate) at 20° C for 1 h after removal of the alcohol.

Table 1. GLUCOSE, FRUCTOSE AND SUCROSE (PERCENTAGE OF FRESH WEIGHT) IN THE FRUIT OF SOME SPECIES OF *Lycopersicon*

Species	Glucose (%)	Fructose (%)	Sucrose (%)	Glucose/fructose ratio
Sub-genus *Eulycopersicon*				
L. pimpinellifolium (B6009)	1·21	1·56	0·16	0·78
L. pimpinellifolium (B34)	1·74	1·95	0·11	0·89
L. esculentum var. *cerasiforme*	1·41	1·80	0·08	0·78
'Moneymaker' (mature-green)	1·25	1·30	—	0·96
'Moneymaker' (orange-red)	1·77	1·86	Trace	0·93
Sub-genus *Eriopersicon*				
L. hirsutum	0·24	0·96	3·30	0·25
L. hirsutum var. *glabratum*	0·44	0·70	4·08	0·37
L. peruvianum	0·14	0·65	3·54	0·22

Fruit of *L. hirsutum*, *L. hirsutum* var. *glabratum* and *L. peruvianum*, all of which are included in the sub-genus *Eriopersicon*, contained considerable quantities of sucrose.

In fruit of the two strains of *L. pimpinellifolium* and *L. esculentum* var. *cerasiforme* only very small amounts of sucrose were present, while in the fruit of variety 'Moneymaker' this disaccharide was virtually absent. The almost complete absence of sucrose in English commercial varieties has been noted previously[10].

Fruit of the species of *Eulycopersicon* examined (including those of variety 'Moneymaker'), while having less than 0·2 per cent sucrose, contained between 1 and 2 per cent of both glucose and fructose, giving glucose/fructose ratios of between approximately 0·8 and 1·0. In contrast, fruit from species included in *Eriopersicon* contained relatively little glucose and fructose. Glucose concentrations were particularly low, giving rise to much lower glucose/fructose ratios than those normally encountered. The results for the fruit of *L. peruvianum*, which contained the lowest glucose and fructose concentrations, are at variance with Luckwill's comment in his investigation of the genus *Lycopersicon*[2]. He states: ". . . the fruits [of *Eriopersicon*] are rich in reducing sugars and in some species (that is, *L. peruvianum*) their taste resembles that of the cultivated tomato. The fruits of other species, however (that is, *L. hirsutum*), have a 'bitter-sweet' flavour due to the presence of solanine . . .". It would appear from the present results that the sweetness of the fruit of these species is due primarily to sucrose and not to reducing sugars.

The sucrose content of the fruit from the progenies of crosses between *L. hirsutum* var. *glabratum* and *L. esculentum* is at present under investigation.

PSYCHOLOGY

Sex Chromosome Abnormalities in Two State Hospitals for Patients requiring Special Security

THE association between sex chromatin abnormality and mental sub-normality is well established. The incidence of sex chromatin abnormality in the new-born male and female population is about 0·2 per cent and 0·08 per cent respectively; in institutionalized mentally sub-normal male and female populations about 1 per cent and 0·4 per cent respectively. Court Brown[1] reported that a high proportion of sex chromatin positive males recognized in his unit had been committed to a mental defective institution because of anti-social behaviour. He suggested that an abnormal sex chromosome complement might predispose to delinquency. However, a survey by Wegman and Smith[2] on a group of socially disturbed males of relatively normal intelligence failed to show an increase in sex chromatin abnormality.

These observations prompted us to undertake a survey of the sex chromatin pattern in a group of the mentally sub-normal who had been 'institutionalized' because of anti-social behaviour. Since this study was begun a report of a similar survey has appeared[3].

Rampton and Moss Side Hospitals are State hospitals for patients who require special security on account of persistent violent or aggressive behaviour. The patients are mentally sub-normal and have been referred by the Courts or transferred from other mental institutions. Twenty-one sex-chromatin-positive males were detected among 942 male patients, an incidence of 2·2 per cent. Two of the 420 female patients examined had two sex chromatin bodies, an incidence of 0·49 per cent. On examining the chromosomes, twelve of the twenty-one sex-chromatin-positive males had 47 chromosomes and an *XXY* sex chromosome constitution. Seven had 48 chromosomes and an *XXYY* complement. Two male

patients were presumed to have *XXY/XY* mosaicism. The majority of the cells analysed for chromosome complement in both female patients with two sex chromatin bodies had 47 chromosomes. Both female patients had a sufficiently large percentage of cells with 46 chromosomes to indicate the presence of *XXX/XX* mosaicism.

The frequency of sex-chromatin-positive males at Rampton and Moss Side Hospitals is compared with the frequency of similar males in other institutions for the mentally sub-normal in Table 1. There is a statistically significant excess of sex-chromatin-positive males at Rampton and Moss Side when compared with institutionalized mentally sub-normal populations where persistent violent or aggressive behaviour is not a feature ($\chi^2 = 21{\cdot}7$, $n = 1$, $P < 0{\cdot}001$). The incidence at Rampton and Moss Side does not differ significantly from that in a similar population in Sweden (Table 1). The frequency of females with two sex chromatin bodies is not significantly different from that observed in other institutions for the mentally sub-normal (Table 2).

It is thus tempting to refer the increased incidence of sex-chromatin-positive males to violent or aggressive behaviour. It was, however, noted that the patients at Rampton and Moss Side have a higher intelligence quotient (mean $77{\cdot}3 \pm 14{\cdot}07$) than patients in other institutions for the mentally sub-normal. Since it is recognized that the incidence of sex-chromatin-positive males among the institutionalized mentally sub-normal is proportional to the intelligence quotient[4–7], being highest in the range of more than 50, it might be expected that a higher frequency of sex-chromatin-positive males would be found in Rampton and Moss Side than in other institutions for the mentally sub-normal. None the less the unusual distribution of the type of sex chromosome abnormality observed suggests that the observed high incidence is not simply a reflexion of higher intelligence quotient. There is an extraordinary excess of individuals with an *XXYY* chromosome complement (Table 3). Indeed, it may reasonably be suggested that this high incidence at Rampton and Moss Side is attributable entirely to an excess of patients with two *Y* chromosomes.

Table 1. Frequency of Sex-Chromatin-Positive Males in Institutionalized Mentally Sub-normal Populations

Population	Total No of patients	No. of sex-chromatin-positive patients	Incidence %
Institutions for the mentally sub-normal without persistent violent or aggressive behaviour (refs. 4–6, 8–13)	10,685	90	0·84
Rampton and Moss Side. Hospitals for the mentally sub-normal requiring special security on account of persistent violent or aggressive behaviour	942	21	2 2
Criminal or hard to manage males of sub-normal intelligence. Forssman and Hambert (ref. 3)	760	15	2 0

Table 2. Frequency of Females with Two or More Sex Chromatin Bodies in Institutionalized Mentally Sub-normal Populations

Population	Total No. of patients	No. of patients with 2 or more sex chromatin bodies	Incidence (%)
Institutions for the mentally sub-normal without persistent violent or aggressive behaviour (refs. 10–12, 14–16)	6,047	24	0·40
Rampton and Moss Side. Hospitals for the mentally sub-normal requiring special security on account of persistent violent or aggressive behaviour	420	2	0 49

Table 3. Types of Abnormal Sex Chromosome Complement found in Sex-Chromatin-Positive Males

Population	Chromosome complement *XXY*	*XXYY*	Other	Total
Babies				
Maclean *et al.* (ref. 17)	12	1	5	18
Institutionalized mentally sub-normal				
Maclean *et al.* (ref. 10)	16	2	10	28
De la Chapelle (ref. 11)	5	0	1	6
Rampton and Moss Side	12	7	2	21

The nature of offences committed prior to admission by the 21 sex-chromatin-positive male patients at Rampton and Moss Side was compared with the behaviour patterns of a randomly selected group of controls from the remainder of the Rampton population. No statistically significant difference in behaviour pattern between these two groups of patients was observed. However, certain trends are suggested. The sex-chromatin-positive patients tended to abscond more frequently than the controls and they committed less homosexual or heterosexual offences. There were no significant differences in type of behaviour disorder between the *XXY* and *XXYY* patients.

Features of Klinefelter's syndrome were present in each of the patients with a simple *XXY* or *XXYY* chromosome complement. The patients with an *XXYY* sex chromosome complement were taller than those with an *XXY* complement, but the difference is not statistically significant. The difference in height is entirely due to the Pubic-Sole measurement and becomes significant if previously reported cases[18,20] are taken into account. The mean measurement for patients of karyotype *XXY* is 89·4 cm ($\sigma = 5{\cdot}67$, $n = 76$) and for patients of karyotype *XXYY* 94·8 cm ($\sigma = 7{\cdot}7$, $n = 16$). This confirms the suggestion by Barr[18] and Bray and Josephine[19] that the extra *Y* chromosome has some effect on growth. The two patients with *XXY/XY* mosaicism had normal-sized testes and normal secondary sex development.

We thank Dr. J. N. McDougall, medical superintendent of Moss Side Hospital, for permission to study the patients in his care and to the medical and nursing staffs of Rampton and Moss Side Hospitals for their full co-operation. This investigation was supported in part by a grant from the National Spastic Society.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, February 7

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. G. M. Berlyne: "The Treatment of Chronic Renal Failure".*

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m —Mr. W. S. Metcalf: "Radio Astronomy".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. E. A. Mason: "The Chemical Industry of Japan".

INSTITUT FRANÇAIS DU ROYAUME-UNI (at Queensberry Place, London, S.W.7), at 8.15 p.m.—French Scientific Films.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Dr. Peter Beighton: "Easter Island People".

Tuesday, February 8

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. Jane Abercrombie: "Educating for Change".*

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. A. H. S. Megaw: "Excavations in Euboea, Kythera, and the Cyclades".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine, 26 Portland Place, London, W.1), at 5.30 p.m. —Mr. A. G. Strong: "Sealants"; 7 p.m.—Mr. A. Randell: "Surlyn A Ionomer Resins".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Sir Lawrence Bragg, O.B.E., M.C., F.R.S.: "Properties of Matter II". (Afternoon lecture for Sixth Form Boys and Girls from Schools in London and the Home Counties. To be repeated on February 9, 15 and 16.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. C. Rashbass: "The Control of the Direction of Gaze". (Eighth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

Wednesday, February 9

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Dr. L. E. Glynn: "The Role of Auto-Immunity in Pathogenesis".*

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.E./I.E.R.E. COMPUTER GROUPS (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. F. G. Heath, Mr. M. G. Hartley, Mr. D. Green and Mr. S. Saleeb: "The Manchester Digital Traffic Simulator".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO ACOUSTICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Mr. A. R. Rangabe: "Trutrack—a New Approach to Low Side Thrust Transcription Arms".

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, London, S.W.7), at 6 p.m.—Mr. F. E. Duffield: "Transducers for Instrumentation".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—NUTRITION PANEL (at 14 Belgrave Square, London, S.W.1), at 6 15 p m —Dr. L. Golberg: "The Toxicology of Food Additives—The Present Position".

CROYDON NATURAL HISTORY AND SCIENTIFIC SOCIETY (in the Maple Room, Fairfield Halls, Croydon), at 7.30 p m.—Dr. G. P. L. Walker: "Some Aspects of Atlantic Geology".

Thursday, February 10

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. L. E. Westrum: "Views of Polynesia".*

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. R. A. Hinde, F.R.S.: "The Use of Sub-Human Primates for Studying the Effects of the Early Social Environment on Later Behaviour".

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. J. G. Withers and Mr. L. Martland: "The Relationship Between the Oil and Automotive Industries".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. H. J. Evans: "Actions of Radiations on Chromosomes". (Ninth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation)*

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m —Mr. G. Cox: "The Independent Television News Service".

Friday, February 11

INSTITUTE OF RURAL LIFE AT HOME AND OVERSEAS (at Friends International Centre, Courtauld House, Byng Place, London, W C 1), at 1.15 p.m. —Miss Helen M. Wallis, M.B.E.: "The Women of Sarawak".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. S. Brenner, F.R.S.: "The Genetic Code".

Saturday, February 12

BRITISH MICROCIRCULATION SOCIETY (at the Wolfson School of Nursing, Westminster Hospital, Vincent Square, London, S.W.1), from 10.30 a.m. to 6 p.m.—Papers in the general fields of "Microcirculation and Biorheology".

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mrs. Charmian Biernoff: "Sorkun—a Village of Potters in North West Turkey" *

Monday, February 14

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 5.15 p m.—Prof. Theodor Bücher (University of Munich): "Dynamics of Liver Metabolism". (Further lecture on February 17.)*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. James D. Ebert (Carnegie Institution of Washington): "Interacting Systems in Development: I. Beyond the Ribosome".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

CHAIR OF COMPUTING SCIENCE—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (February 12).

LECTURER (with a good degree in physiology, biochemistry, pharmacology, chemistry, medicine or zoology) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Deputy Secretary, The University, Southampton (February 12).

LECTURERS (2) (preferably specialized in either urban geography or Latin America) IN GEOGRAPHY—The Secretary of the University Court, The University, Glasgow (February 13).

LECTURER IN THE DEPARTMENT OF PHYSIOLOGY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 14).

LECTURERS (2) IN ENGINEERING MATHEMATICS—The Registrar, The University, Newcastle upon Tyne, 2 (February 14).

RESEARCH ASSISTANT (male or female honours graduate in any of the biological sciences including medicine) IN TISSUE CULTURE IN THE DEPARTMENT OF ANATOMY—The Registrar, University College, Cathays Park, Cardiff (February 14).

SENIOR LECTURER IN SOCIOLOGY—The Registrar, University of Warwick, Coventry, Warwickshire (February 18).

LECTURER IN EDUCATION COMBINED WITH PHYSICAL SCIENCES; and a LECTURER IN EDUCATION COMBINED WITH BIOLOGICAL SCIENCES—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (February 19)

ASSISTANT (preferably with a special interest in human geography) IN GEOGRAPHY—The Secretary and Bursar, University College, Dublin, Republic of Ireland (February 21).

LECTURER IN STEROID BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (February 21).

LECTURER (with a distinguished academic record in pure mathematics, applied mathematics or statistics) IN THE SCHOOL OF MATHEMATICS, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 25).

LECTURER IN MEDICAL PHYSICS—The Registrar, The University, Manchester, 13, quoting Ref. 12/66 (February 26).

LECTURER IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, The University, Aberdeen (February 26).

LECTURER (with a special interest in enzymology) IN BIOCHEMISTRY—The Registrar, University College of Swansea, Singleton Park, Swansea (February 26).

LECTURER (graduate in science, pharmacy or medicine) IN PHARMACOLOGY —The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (February 28)

LECTURER TO SPECIALIZE IN BIOCHEMISTRY—The Registrar (Room 39, O.R.B.), The University, Reading (February 28).

LECTURER (with a good degree, preferably with honours, and well qualified and experienced in the teaching of one or more of the following subjects mathematics, biology or chemistry) IN THE DEPARTMENT OF EDUCATION, University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, February 28).

LECTURER (with either teaching or industrial experience in the physical aspects of pharmaceutics, together with a strong interest in research) IN PHARMACEUTICAL TECHNOLOGY—The Registrar, University of Strathclyde, Glasgow, C.1 (February 28).

LECTURER (with qualifications in approximation theory or related branches of mathematics) IN MATHEMATICS—The Secretary, University of Lancaster, Bailrigg House, Lancaster (February 28).

LECTURERS (2) IN BACTERIOLOGY/IMMUNOLOGY at the Western Infirmary —The Secretary of the University Court, The University, Glasgow (February 28).

CHAIR OF EDUCATION—The Secretary, Trinity College (University of Dublin), Dublin, Republic of Ireland (March 1).

TUTORIAL RESEARCH STUDENT (man or woman) IN PHYSICS (Experimental or Theoretical)—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey (March 1).

LIBRARIAN at Ahmadu Bello University, Northern Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (March 2)

LECTURER/SENIOR LECTURER (preferably with experience in the control of computer installations carrying out a variety of scientific computations on a service basis) IN THE BASSER COMPUTING DEPARTMENT, School of Physics, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 4).

LECTURERS (2) (with a degree in bacteriology or equivalent qualifications) IN BACTERIOLOGY—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (March 7).

READER and SENIOR LECTURER IN THE DEPARTMENT OF MATHEMATICS, PURE AND APPLIED, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 15).

LECTURER or SENIOR LECTURER IN PLANT PHYSIOLOGY at Lincoln College (University of Canterbury), New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, March 31).

UNIVERSITY LECTURER and a UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF ANIMAL PATHOLOGY in the School of Veterinary Medicine—T. D. Kellaway, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge (March 21).

LECTURER IN PARASITOLOGY (Immunology) at the University of Queensland, Brisbane, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, April 1).

LECTURERS (preferably with research experience in one of the following fields: experimental cytology, developmental biology, comparative physiology or protozoology) IN ZOOLOGY—The Secretary of the University Court, The University, Glasgow (April 1).

UNIVERSITY RESEARCH FELLOW IN THE HISTORY AND PHILOSOPHY OF SCIENCE IN THE DEPARTMENT OF PHILOSOPHY—The Registrar, The University, Leeds, 2 (April 4).

ASSISTANT LECTURER to assist in the teaching of general geology as part of a scheme of study in earth sciences—The Registrar, University College of North Wales, Bangor, North Wales (April 30).

SECOND CHAIR OF ELECTRICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea (April 30).

CHIEF TECHNICIAN IN THE DEPARTMENT OF ZOOLOGY, to be in charge of the technical staff (25) of the laboratories—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh, quoting Ref. No. CT/Z/1/66

MASTER TO TEACH MATHEMATICS WITH SUBSIDIARY PHYSICS; and a MASTER TO TEACH PHYSICS—The Headmaster, Epsom College, Epsom, Surrey.

PHYSICAL CHEMISTS (young graduates) to do research in inorganic thermochemistry and thermodynamics and on vapour phase reactions, partly at high temperature—The Director of Research, Fulmer Research Institute, Stoke Poges, Bucks.

RESEARCH ASSISTANT (biologist) to take part in a programme concerned with embryonic nutrition and its relation to congenital malformations—Dr. E. Beck, Department of Anatomy, University College of South Wales and Monmouthshire, Newport Road, Cardiff.

TECHNICIAN OR JUNIOR TECHNICIAN (preferably with previous experience in sterile techniques and/or tissue culture) IN THE CHROMOSOME UNIT OF THE NUFFIELD UNIT OF MEDICAL GENETICS, for work on human chromosomes—The Registrar, The University, Liverpool, 3, quoting Ref. 412/N

WATER SUPPLY GEOLOGIST (between 30 and 45, national of, and resident in, the United Kingdom or the Republic of Ireland, with an honours degree in geology and at least five years experience in water supply geology, including electric logging of bore-holes) in Nigeria, to supervise water supply exploration drilling projects and to train young Nigerian geologists—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 218/130/02.

Progress in Spectroscopy

Unicam SP800 Spectrophotometer with automation accessories

Save operator time, increase speed and efficiency with Unicam automation for:

ENZYME REACTION RATES

LIQUID COLUMN CHROMATOGRAPHY

ALL ROUTINE ULTRAVIOLET & VISIBLE SPECTROSCOPY

Send for descriptive brochure.

Among the many important applications for the Unicam SP800 Spectrophotometer none is a better example of its potential than the measurement of enzyme reaction rates. For this the Automation Accessories are vital components. Other widely acclaimed features are the Flat Bed Recorder, the Beam Balance Smoothing Cam and the unique Second Sample Position, all of which mark the SP800 as the outstanding U.V. and Visible Recording Spectrophotometer. The Automatic Equipment provides:
AUTOMATIC interchange of up to 4 sample and 4 reference cells,
AUTOMATIC re-cycling over any pre-selected wavelength range,
AUTOMATIC recording at predetermined time intervals.

HENDREY SPARK RECORDER Type 1487A

Compact and weatherproof, this single channel recorder is light in weight and easily portable. The Perspex window gives a clear view of the heat-sensitive chart for approximately 6 in. of its length.

The instrument can also be used mounted on bench, wall or panel and is supplied with mounting plate incorporating three anti-vibration mountings which render the instrument shock-proof and vibration-proof to service standards.

An electro-magnetically operated stylus, operated by a separate switch not supplied with the recorder, provides transverse markings near the edge of the chart. Provision is made for an external alarm circuit which can be pre-set to operate at any deflection from zero to full scale by means of a control on the case.

Sensitivity—50 *micro-amps. Full scale. Supply*—12 *Volt, D.C.*

ELECTRICAL AND ELECTRONIC EQUIPMENT FOR THE SERVICES

THE seventh report from the Estimates Committee for the session 1964–65*, dealing with electrical and electronic equipment, is of far wider scientific interest than its formal subject might suggest. The Sub-Committee which examined the Defence Estimates and relevant sections of the Civil Estimates, more particularly the Votes for the Ministry of Aviation, was told by one witness that electronics was a technique, a modern technology in the same sense as hydraulics or mechanics. Moreover, while equipment such as radar sets can be clearly defined as electronics, other equipment which may embody electronic techniques cannot be regarded solely as electronic. It was difficult for the Sub-Committee to determine with any accuracy how much was spent by or for the Services on electrical and electronic equipment; furthermore, much of the expenditure on research and development, borne largely by the Ministry of Aviation, was regarded as classified and could not be published.

In encountering this problem of security the Estimates Committee touches on one of the aspects of its enquiry that is of major scientific interest. There is indeed nothing new about the practical difficulties of security which confronted the Committee, and its approach is eminently sensible and reasonable. In its fourth report, for the session 1946–47, the Select Committee on Estimates noted the reluctance of departments to supply information on defence matters, and the present Committee recognizes that there has since been some improvement. It also recognizes that, from the point of view of security, electrical and electronic equipment is a highly sensitive subject: it would be wrong to seek to disclose, for example, details of research in progress at the research establishments of the Ministry of Aviation. The Committee did not find it easy to determine in all cases what was or was not secret or confidential, and respect for or deference to the views of the department concerned has necessarily restrained some of the Committee's comments. Inevitably, this has to some extent diminished the impact of those comments.

The Committee itself is not entirely satisfied with this situation and is far from convinced of the necessity for secrecy on, for example, levels of stockholding or siting of equipment. Furthermore, a department was, on occasion, forced to admit the absence of any real reason for its request that certain evidence should not be published. The enquiry also brought to light the existence of clear inconsistencies between the defence departments.

The Committee was not, however, so much concerned about the problems caused by such unnecessary security. Its real anxiety arises from the danger to national security which this practice presents. As the Estimates Committee rightly emphasizes, regular classification of information which can safely be disclosed causes the system to become meaningless and brings it into disregard. As a result, information of a really secret nature ceases to have adequate protection. The importance of this point was made in the Radcliffe Report on Security Procedures in the Public Service and more recently, by implication, in the report of the Standing Security Commission.

The Estimates Committee is content to leave the question of security procedures with the remark that a realistic approach to security classification in the defence departments and the Ministry of Aviation is essential for proper control of really secret information. Too often there is a general tendency for departments to classify certain information and to refuse to disclose it, not because disclosure would prejudice national security, but because it might involve departmental inconvenience. The Committee might have added that security depends not so much on an appropriate mechanical system as on intelligence and continued hard critical thinking which, as already noted, restricts the classified material to the essential minimum.

Scientists and technologists, who are well aware of the vital need for informed public discussion of so many of the issues raised by the invention and development of scientific equipment, should be grateful to the Estimates Committee for the clarity and firmness with which this vital issue is presented. The view of the Committee that it is entitled to as much information as possible, consistent with national security, is reasonable; the request is made, moreover, in a context which indicates full awareness that this information will form the basis of public discussion. In the field of electronics, informed discussion in Britain has been handicapped by information which is inadequate when compared, for example, with that given to the Congress of the United States. As a Parthian shot, the Committee points out that, with rapidly evolving techniques, a piece of electronic equipment may be highly secret one year and almost obsolete the next. The first of the Committee's twenty-one recommendations is that a thorough-going review should be undertaken of the security classification of electrical and electronic equipment for the Services, including the desirability of regular re-classification after a lapse of time. This recommendation calls for immediate implementation by any Government professing to be concerned with economic efficiency as well as security. It is no party issue and the Parliamentary and Scientific Committee might well press the matter firmly.

The next issue raised in this report of prime concern to the scientist and technologist is that of research. This is considered at some length in the section of the report which deals with the system for obtaining equipment, and behind the Committee's approach is a concern with the failure of present procedures to overcome the difficulties caused by constantly increasing costs which may be one cause of delay in bringing a project to fruition. The history and cost of any project begin with research, and for electrical and electronic equipment the cost and responsibility for research are borne almost entirely by the Ministry of Aviation. The function of the research programme of the Ministry is briefly described, in a memorandum submitted in evidence, as consisting of research in support of projects to meet operational requirements and general research with the object of increasing the Ministry's knowledge and authority to

* Seventh Report from the Estimates Committee, together with part of the Minutes of the Evidence taken before Sub-Committee C, Appendixes and Index, Session 1964–65. *Electrical and Electronic Equipment for the Services*. Pp. liii+275. (London: H.M.S.O., 1965) 27*s*. 6*d*. net.

assist in formulating future requirements and in supervising development work carried out by industry.

The research work is undertaken largely within the Ministry's own establishments, although contracts are placed with industry for the investigation of particular aspects. The establishments concerned with electronic research and development are the Royal Radar Establishment at Malvern, the Signals Research and Development Establishment at Christchurch and the Radio Department at the Royal Aircraft Establishment, Farnborough. The Estimates Committee was concerned mainly with the direction of this effort, and its division between industry and these establishments of the Ministry of Aviation. It admits that secrecy considerations hindered the discussion of specific questions, since neither the nature nor the cost of certain research could be disclosed.

The Ministry's research and development programme is controlled within the department by the Research and Development Board, of which the Permanent Secretary is Chairman and on which the Central Department of the Ministry of Defence is represented, while representatives of the Service Departments attend as necessary. Other members of the board are the Chief Scientist, the Deputy Secretaries, the Controller of Aircraft and the Controller of Guided Weapons and Electronics. The two Controllers are executively responsible for the research, development and production programmes, while the Chief Scientist, advised by the Directors-General of Research and Development and the various Directors of Research, is responsible for co-ordinating the broad research programme of the Ministry as a whole. There is close day-to-day liaison between the Ministry of Defence Departments and the Ministry of Aviation in formulating requirements, and this close association continues throughout the development programmes. Altogether, nearly eleven hundred professional and technical staff are engaged at the headquarters and at other establishments of the Ministry in supervising aimed research, development and production of electrical and electronic equipment.

Each Director-General reviews his technical area at half-yearly intervals, the Chief Scientist dealing with all his establishments on an annual basis. There is also the Electronics Research Council, which includes eminent scientists in the field of electronics, as well as representatives from the Ministry of Aviation and the Ministry of Technology. Formally, the Electronics Research Council reports to the Minister of Aviation, but in practice its work is seen essentially as feeding in new ideas for research.

Expenditure on research in the establishments of the Ministry of Aviation increased during 1964–65 and is greater than that on research contracts with industry, although representatives of the Electronic Engineering Association suggested in evidence that industry, from its own funds, was spending between £3 million and £4 million a year on research. This sum is distinct from that expended by the Ministry on research contracts with industry, which is described as an "adjunct of the research programme of the establishment which sponsors the contracts". Expenditure on research contracts with industry has not varied greatly in recent years, although it was stated in evidence to the Committee that it was the policy of the Ministry of Aviation to increase the amount of research undertaken in industry and that this was being carried out.

The Estimates Committee recognizes the importance of ensuring that there is no wasteful overlapping in the research carried out by the Ministry's establishments and by industry, and that the Ministry is fully aware of what is happening in industry, not only with regard to research contracts sponsored by the Ministry but also in the general programme of industrial research. Some duplication of effort between individual firms may be desirable: a witness from the Electronic Engineering Association thought that some duplication of research before a problem was solved might be beneficial because, on occasion, one of several teams might arrive at a solution which would be missed by another team. Duplication of effort between the Ministry of Aviation and industry in the field of specific research contracts is another matter, but neither the Ministry nor the industry considered that such undesirable duplication existed. The flow of information from the research establishments to industry was regarded as good and the research establishments of the Ministry were said to have a remarkably wide knowledge of what was going on in industry. Rightly, the Estimates Committee insists that this awareness must continue to be maintained and it regards a regular series of progress reports from all electronics firms, given in close confidence, to be an essential part of the research planning of the Ministry of Aviation.

The extent to which Government-sponsored research should be undertaken by industry is a difficult question. The Electronic Engineering Association accepted that some research must be carried out in Government establishments but, at the same time, thought that industry should continue to conduct a fair proportion of research, particularly in materials and where the techniques, the technology and the knowledge lay close to the production process and the knowledge of industry. Here industry is generally better equipped to visualize the commercial prospects arising from particular lines of research and to exploit them. On the other hand, in general research it is essential for Government establishments to possess systems experts who are familiar with all the broad complex of new equipment and its techniques, and who are competent to consider how such equipment can be brought together into a coherent whole. Nor, again, can the Ministry of Aviation's establishments supervise the technical work on development of equipment by industry unless they possess the knowledge and authority derived from participation in such research.

The Estimates Committee recognizes the force of these arguments but, without lessening the control of expenditure exercised by the Ministry of Aviation, it suggests that the number of individual research contracts given to industry might be increased with advantage. It is also possible that research in a given field may enable a firm, which in any event may have to carry out the development programme for the project, to increase its proficiency and thus lessen the eventual cost of development. The second recommendation of the Committee is, accordingly, that the Ministry of Aviation should review the programme for individual research projects with the view of increasing the proportion of contracts placed with industry.

The most crucial phase in the procurement of equipment is development, and the next section of the report deals in some detail with the three main phases towards full development. Before considering recommendations of the Committee here, it may be as well to note some questions regarding organization on which, for all their restraint, it was apparent that the Estimates Committee had some reservations, if not misgivings. Its enquiry into the organization of research failed, for example, to elucidate the position or function of the Chief Scientific Adviser. It would seem from the Minutes of Evidence that the

relations of the Ministry of Aviation and the Ministry of Defence may well have prevented him from conducting just such an enquiry as the Estimates Committee was led to make.

The whole picture of ministerial relations which the report presents is one of confusion. This extends to the Ministry of Technology also and to the Ministry of Education and Science, embracing besides the Electronics Research Council, the Science Research Council and the Advisory Council for Technology. There is evidence of a lack of clear thinking on organization which almost certainly must handicap effective management and control, and not even the Estimates Committee could withhold comment as to the nebulous function of the Ministry of Technology as the sponsor of the electronics industry. It points out, indeed, that the Treasury and the Stationery Office are also involved with computers but it maintains firmly that removal of this function of sponsorship from the Ministry of Aviation enlarges the gap between military and civil uses of electronics. This is the opposite of what is desirable, and such weighty criticisms will scarcely strengthen confidence in the wisdom of extending the sponsorship responsibilities of the Ministry of Technology to the electrical industry as a whole.

The Estimates Committee was convinced that the present division of departmental responsibility does not lend itself to the bold decisions which are necessary. The Committee felt that extensive reorganization of the structure of the departments is essential if they are to cope with the ever-increasing complexities of one of the most rapidly evolving technologies. The structure of Britain's research effort in civil science cannot yet be regarded as settled, perhaps even less its relation with Britain's effort in defence research. The most effective means of control and of efficient use of trained manpower has still to be established, and in the light of this enquiry the value of the changes made in the past two years is still unproven.

In this context it should not escape notice that in the December issue of *State Service* the Institution of Professional Civil Servants makes strong representations to the Ministry of Technology that, unless urgent consideration is given to an alternative role in the civilian field, resources and staff at Aldermaston are in danger of being frittered away. In this article, Mr. J. Lyons advances the idea that Aldermaston might become a major regional laboratory for engineering technology, basing the proposal on Aldermaston's ability to undertake prototype work for industry, specializing particularly in metallurgical, mechanical, electronic and computer applications. It could undertake contract work which industry is not equipped to handle and in this way Aldermaston could be developed into a centre available not only to industry but also to universities, colleges of technology and Government departments.

Mr. Lyons presents a reasoned argument, and the way in which the Minister of Technology handles this problem of an alternative role for Aldermaston may well be a touchstone of his own competence. Neither the Ministry of Defence nor the Ministry of Technology is shown in a good light by the Estimates Committee's examination of development in the present report, although the Committee recognizes that the adopted procedures do, in fact, follow the ideas laid down in the Zuckerman Report on the Management and Control of Research and Development. The main object of the Zuckerman Report was to emphasize the importance of the project investigation as a basis of decision whether or not to proceed to full development. The Committee admits that these procedures have inherent difficulties in the correct estimation of cost and in the time factor involved, speed being essential if rising costs are to be avoided.

The Electronic Engineering Association suggested that the Zuckerman procedures might be accelerated by more research in techniques in advance of a project programme, by close co-operation between the Ministry and industry, and by an effort, during the feasibility study or project study, to resolve the major points towards the end of the time allotted for the study. The Ministry of Aviation accepted the first suggestion, with a minor qualification, and the Estimates Committee believes that their recommendation for increasing the number of research contracts in industry will also help. In spite of reservations by the Ministry of Aviation and the Ministry of Defence, the Estimates Committee was unconvinced that the decisions could not begin to be taken at a rather earlier stage, as proposed in the third suggestion. Accordingly, it recommends that, wherever possible, interim reports of feasibility studies and project studies should be made so as to facilitate preliminary decisions whether to proceed to the next phase.

The Estimates Committee was not entirely satisfied with the amount of control exercised by the Ministry of Aviation over the development contract. This is of the highest importance not only because of the expense involved in development and the need to ascertain costs accurately as soon as possible but also because of the very close link between development costs and costs of production. The Committee recommends, therefore, that the Ministry of Aviation should, in consultation with the Treasury, ensure that the Contracts Division is so staffed that a technical cost estimator can be attached to and remain with each major contract throughout its development and production phases. It also recommends that the Ministry should seriously consider the further reorganization of the staffing of this Division.

These are probably the major recommendations of the Estimates Committee, as they are those of the greatest scientific and technical interest, though the principle of the research and development levy, fixed as a percentage of the selling price on any goods sold to third parties, is questioned, and a review recommended in relation to the exports of electrical and electronic equipment. For the rest, the Estimates Committee's report touches on production and inspection, reviews the system in practice and the control and handling of electrical and electronic equipment in service, more especially the use of automation in storekeeping and the future programme for computers for the Services. It touches on the difficult problem of the interdependence of the purchase of foreign equipment and exports and most of its recommendations relate to these matters.

Nevertheless, the main value and interest of this report from the Estimates Committee lies first in its searching comments on secrecy and security procedures, and secondly in the questions which it raises regarding the organization of research and its relation to development. It is here that the critical issues lie: here also are tested the competence as well as the organization of departments. What stands out above all is the need for some clear and unprejudiced thinking on all these issues, for constructive criticism as well as open-mindedness, for a readiness to reconsider in fact whether the independent existence of particular Ministries like those of Technology and of Aviation is really justified, and whether the functions of these Ministries would not be more appropriately redistributed in the Ministry of Defence and elsewhere.

(London: The Institution of Mechanical Engineers, 1965.) 160*s*.

DR. J. W. CHRISTIAN has produced a magnificent work of scholarship which must have occupied many years of investigation. *The Theory of Transformations in Metals and Alloys* is at once, at an advanced level, both a text-book for those interested in transformations, and a reference book for a wide range of research workers. The approach is totally different from those of past authors. Classification and definition of transformations occupy a chapter, since the author includes many solid-state changes and not only phase reactions. His preface claims, rightly, to include "every major kinetic effect in physical metallurgy and solid state physics, with the notable exception of plastic deformation by slip". Twinning is included, and lattice defects, since they are involved in martensitic transformations and diffusion.

The discussion is exceptionally well done in the standard text-book topics of lattice geometry, point defects, boundaries, and diffusion. The author has used vector analysis and matrix algebra, particularly the latter, but has also illustrated the main points to give a corresponding physical picture whenever possible. As the author suggests, undergraduates in honours schools should be capable of coping with the text, but graduate students are likely to be the main readers.

To take one example from this book, the classical theories of nucleation and growth processes are followed by a chapter on transformation kinetics, and a gentle follow through to growth of crystals from the vapour phase and on to solidification and melting. This section forms perhaps the most complete treatment of this particular subject ever to appear. References up to 1962 are included, with one or two up to 1964 added in proof. Where little experimental work has been carried out on a particular problem, the author wastes no time on pure supposition, as for example in dealing with the peritectic reaction. Where the reverse applies, as for Guinier–Preston zones in aluminium–copper alloys, a full treatment is given.

Many readers may well consider the book should have been split into two volumes, partly for content, and partly for ease of handling. Already my colleagues are devouring it.

The other two volumes constitute the formal records of international conferences, suitably edited. In the case of *Lattice Defects in Quenched Metals*, the topics centred around the use of a now well-established technique (the increase in lattice defect concentration by quenching from a high temperature) to explore numerous aspects in both metals and alloys. As with any similar technique, where advantage is taken of metastability to explore a material not in equilibrium under the conditions of experiment, the value of the results lies in what can be interpreted by interpolation or extrapolation to different conditions. The papers presented in this volume achieve this end with varying degrees of success, but consolidate the technique as a means of exploring migration and binding energies, distinction between types of defect, and the role of impurity atoms.

Experimental methods have largely overcome the most serious drawbacks, namely quenching strains and contamination of the specimen surface. The majority utilize electrical heating with immersion in liquid nitrogen or helium, quenching resulting from interruption of the heating current. Electrical resistivity remains the most favoured property for investigation of quenched-in defects, with density and stored energy close behind. Perhaps the most rapidly advancing techniques are those of internal friction and transmission electron microscopy of thin foils. Low angle scattering of X-rays is invaluable in work on agglomeration of vacancies or dislocation loops, but presents problems with certain materials. Magnetic measurements, particularly with ferromagnetics, are of value in cold worked and irradiated metals, but less so after quenching.

The majority of papers recorded in this volume dealt with complex vacancy arrangements, that is, clusters associated with dislocations and stacking faults. The simpler forms, with more than two but less than one thousand vacancies involved, are less understood, particularly in their crystallographic character. Body-centred cubic metals were examined in two of the papers but the majority of attention, as usual, revolved around face-centred structures, since these are more amenable to this type of treatment. This volume is a valuable stepping stone to those workers concerned with lattice defects, but will probably be out of date in a few years' time.

The joint international conference on "Creep" attracted three hundred delegates from twenty countries when held in New York, and four hundred delegates from twenty-two countries when repeated in London. Three prestige lectures, two sponsored by the two American institutes (with British speakers) and one sponsored by the Institution of Mechanical Engineers (with an American lecturer), were included in the *Proceedings*.

The subject of creep is of tremendous practical significance in view of the rapid technological advances of the space age, and therefore attracts a wealth of more fundamental work into the background science. This conference covered a very wide range of topics, from the relationships between metallurgical structure and deformation, through plasticity theory, thermal cycling effects, and design data, to the correlation of service data with laboratory tests and the effects of environment. Steels featured prominently as the most common material for this type of service, particularly in power generating stations, but magnesium, aluminium, and nickel-based alloys appeared in the more basic science papers.

Such a variety of materials, methods of approach, and objectives, whether basic or technological, creates a mess of mental pottage from which any attempt to extract a reasonably lucid précis would be both meaningless and impossible. The outstanding differences between the fundamental work and the service problems are such that intermediaries become necessary, to bridge the gap which alternately widens and narrows with succeeding conferences of this kind. Such organizations as the Central Electricity Generating Board and the Atomic Energy Authority in Britain, and the Atomic Energy Commission in the United States, must, and do, provide such liaison. The interpretation of creep parameters in terms of activation energies and dislocation mechanisms requires careful experimentation with near perfect specimens, in order to achieve precision. The use of bulk quantities of steels in power generating equipment involves economic stringency, preventing any close approach to perfection of chemical composition, metallurgical structure or homo-

geneity, quite apart from strict controls or evaluation of stress and temperature. The only parameter which can be measured with the same degree of certainty on both sides is time.

It would not be unfair to say that nothing new came out of this conference in the scientific sense, but in the correlation of creep data with service life, a considerable step forward must result from the additional evidence supplied here.

C. R. TOTTLE

ROCK MAGNETISM TO-DAY

Rock Magnetism

By Prof. Takesi Nagata. Revised edition. Pp. viii + 350. (Tokyo: Maruzen Company, Ltd.; New York: Plenum Press, 1961.) 9.50 dollars.

ROCK magnetism is that branch of geophysics that deals with the origin of magnetization in rocks and its stability. Workers in rock magnetism are also interested in the phenomenon of self-reversal, that is, a rock acquiring a magnetic moment exactly opposed to the ambient magnetic field. It is necessary to point out that almost all the minerals that cause rocks to be magnetic are also electric insulators and often of very high coercivity. This makes them of interest to solid-state physicists as possible permanent magnet materials. It was the work on rock magnetism that first drew Néel's attention to the possible existence of spontaneous reversal of magnetic moments in ferrites. Again, it was the work on the highly unstable red rocks containing haematite (α-Fe_2O_3) that led Néel to the idea of 'Superantiferromagnetism'. In spite of these occasions, when rock magnetism has been responsible for fundamental advances in pure magnetism, it has mostly lagged behind the advancing front of our knowledge of the magnetism of solids. An example of this can be found in the statement that if, when dropped or struck, bar magnets can lose their magnetization, how can rocks retain their remanent magnetization over geological time-scales? To pose this question is to display ignorance of the concept of magnetocrystalline and shape anisotropy in solid-state physics. *Rock Magnetism* is admirable in this and other respects.

This new edition includes references to almost all the new theories and discoveries in the field of magnetism of solids. Even though these references must, of necessity, be brief, they are there to guide the interested and enthusiastic reader. It appears that, compared with the previous edition, the present one has been increased in volume by only a third. This, however, is not the case. There are twelve chapters now instead of the six in the previous edition. Also, some old chapters have doubled or more than trebled in size. This is the case for the chapter on "Outline of Ferromagnetism" and that on "The Natural Remanent Magnetism of Sedimentary Rocks". This is a direct result of the increased application of the new techniques of solid-state physics to rock magnetism, and this trend will continue. Because it is such a fruitful and controversial field of research, many will query some statements made in Chapter 6 on chemical remanent magnetization. The phrase 'chemical remanence' is in itself a misnomer, because, as has been shown by the excellent work done in Prof. Nagata's own laboratory, the new remanence in minerals undergoing a chemical change is produced not as a direct result of the chemical action or ionic migration but due to the growth of new crystallites through critical sizes. To describe it as 'crystallization remanence' would be more appropriate. On page 213 it is claimed that "there is no magnetite in any normal red sandstone". On the contrary, the very extensive work of Van Houten on the sedimentary petrology of these rocks shows the unambiguous presence of magnetite in red beds. Van Houten also shows a curious correlation between the Triassic and post-Triassic rocks, and the abundance of magnetite.

For the benefit of the uninitiated reader it must be mentioned that it can no longer 'safely' be said that all haematite in red beds "has been produced *in situ* by post depositional chemical changes". Similar criticisms also apply to misdirected use of the word 'titanomaghemite'. If this is to be taken to mean, by analogy with titanohaematites, maghemite containing variable amounts of titanium, the titanium reducing the ferric ions but leaving the vacancies alone, it is one thing. But if it is also claimed that titanium fills the vacancies and stabilizes the metastable maghemite, the end-member of such a solid solution of titanomaghemites is a titanomagnetite! If expressed as a solid solution (x Fe_2TiO_4 $(1-x)$ Fe_3O_4) the previously mentioned end-member of the titanomaghemite series will have $x = 0{\cdot}33$. There are also a few minor errors and omissions. On page 64, electromagnets are said to be used to produce strong alternating magnetic fields, and on page 272, Stacey's main conclusion from compression experiments is omitted. This was that as long as the rock has no pronounced anisotropy to begin with, thermoremanence cannot be deflected by pressure applied during geological time.

Such criticisms apart, the volume is sure to prove a valuable source-book of information for geophysicists, geologists and physicists in that order. There are two very satisfactory chapters which deal with the application of rock magnetism to geology, pure and applied. The final chapter, on the history of rock magnetism, is bound to be of great help to future historians of science. In short, this book brings rock magnetism up from the level of a 'stamp collecting' science to the present day. It is up to the geophysicists and physicists to-day to proceed further, to a complete 'take-over' by solid-state physics of rock magnetism. This, indeed, would be an admirable thing.

SUBIR K. BANERJEE

PHYSICAL GEOGRAPHY OF THE OCEANS

The Physical Geography of the Oceans

By Charles H. Cotter. Pp. 317. (London: Hollis and Carter, 1965.) 35*s*. net.

THE publication of *The Physical Geography of the Oceans* is a welcome sign of the increasing awareness of oceanography as an important branch of study, from many points of view. It aims at providing a course in the physical geography of the oceans for students in the sixth forms of schools or in the first year at university. A good deal of basic physical oceanography is covered as well as a more detailed treatment of some aspects of particular interest to the geographer.

The first chapter starts off by taking a global view, describing the distribution of oceans and continents, and going on to give a general account of the bottom topography of the oceans. This is done clearly and adequately for the most part, but it is rather surprising to see that the chart given of the Arctic Basin shows no sign of the Lomonosov Ridge, which divides this region into two distinct sub-basins. The origin of the continents and ocean basins is treated in the next chapter, which leads on from a historical approach to more recent ideas on this subject. There are several points, however, in which the treatment has not been brought up to date. One diagram, for example, shows the earth's crust as being thicker under the ocean than under the continent, contrary to the view now accepted. The boundary regions of the oceans: the coastlines and shores, islands and the ocean bed, including its deposits, are dealt with in several chapters. A separate chapter is devoted to coral reefs and islands, the origin of which provided one of the famous scientific disputes of the nineteenth century and which is a subject of renewed interest to-day.

The weather and climate over the oceans are treated thoroughly, bringing out the interaction between the oceans and the atmosphere and its great importance to both. Ocean currents are treated quite fully, beginning with an account of the physical principles which influence currents of various types and going on to a description of the general circulation of the oceans. This is well done and includes references to some recent discoveries, such as the Cromwell Current in the equatorial Pacific. The chapter on tides, on the other hand, is the least satisfactory in the book. The concept of the equilibrium tide is wrongly defined and the misleading statement is made that the equilibrium tide is so close to the actual tide that tidal predictions are still largely based on the equilibrium theory. It is sad to see that old chestnut, Whewell's 1833 cotidal chart, reproduced as if it had any relevance to modern views of tidal oscillations in the Atlantic. There is a chapter on instruments used in oceanography and the book ends with a rapid historical survey, from Captain Cook to the International Geophysical Year. A few mis-statements occur in various places throughout the book, which may mislead the unwary. Thus the sperm whale is not one of the whalebone whales and it is surprising to see it implied that nitrogen is needed for the formation of carbohydrates. It also seems a mistake to say that metallic sodium is extracted from the sea on a commercial scale. These are minor criticisms, however, of a book which should succeed in interesting many of the younger generation in the scientific study of the seas.

MEDICINE FOR ALL

Medicine in Modern Society

Medical Planning Based on Evaluation of Medical Achievement. By Prof. Thomas McKeown. Pp. 234. (London: George Allen and Unwin, Ltd., 1965.) 35*s*. net.

So much of modern medicine has grown up in a fragmentary and empirical manner that it is more than refreshing to find a book where the concern is only to promote a total medical service which will most efficiently satisfy the needs of society as a whole. To evaluate the existing overall position and to lay down guide-lines for the future, Prof. McKeown examines, in *Medicine and Modern Society*, the way in which our medical services have developed over the past three hundred years and the contributions they have made to the improvement of health. The main influences responsible for the advance of health have undoubtedly been the rising standard of living since 1770, associated with the industrial revolution, as well as the control of the physical environment (water, sewage and housing) from about the 1870's. These influences have been accelerated in the present century and have been assisted by specific medical measures applied to the individual, most of them arising from control of infectious diseases and from the discovery of new forms of chemotherapy. Except as a means of spreading knowledge, the contribution of the medical practitioner to improvement of health has been relatively slight; his main concern has been with the alleviation of pain and suffering.

To-day, the predominant medical issues which face technically advanced countries like Britain are those determined at the time of birth (abortions, foetal and early post-natal deaths, congenital malformations and disabilities), mental illness at all ages, and disease and disability associated with ageing. Since the control of inheritance has contributed little or nothing of practical value in the advance of health, the present-day medical problems are likely to yield most to the manipulation of the physical environment and the prevention and treatment of disease in the individual. As McKeown so rightly points out, further advance is anticipated in both these directions and from modifications of personal habits injurious to the health of the individual (excessive smoking, consumption of alcohol, faulty nutrition) or of social behaviour which adversely affects the health of others (atmospheric pollution, excessive noise, job monotony). Despite these advances, however, many individuals (those handicapped from birth or mentally ill and the aged) will be left with periodical illnesses, and their continued treatment will need extensive medical care and treatment.

To cope with all these demands, the expansion of medical services must be considerable. They should not be allowed to develop in the fixed pattern of earlier years, which, as this careful analysis shows, has led to "the separating of general, chronic and mental hospitals, the isolation of domiciliary from institutional medical care (due mainly to the relationship established between general practitioner and consultant) and the separation of preventive medicine under a public health service from the treatment services provided by general practitioner and hospitals".

McKeown's long-term proposals for medical services are not unexpected. He recommends a balanced hospital community where all facets of hospital work are brought to the same site and where there is a common medical and nursing staff assigned to patients whose hospital care is not completed in an acute unit (particularly psychiatric and geriatric patients). Health centres should be staffed by groups of doctors and related health workers providing facilities complementary to the out-patient department of hospitals, which they would relieve of patients not requiring the hospital's special facilities. The relationship of consultant to general practitioner should be considerably modified; 'general' practitioner should disappear and be replaced by 'personal' doctors, who would provide care in patients' homes, health centres or hospitals and who would specialize either in obstetrics, paediatrics, as general physicians, or in geriatrics. A new type of administration of medical services is needed although the local authority 'population' approach to medical services and due emphasis on preventive measures should be retained. Prof. McKeown also recommends a complete re-orientation of medical education so that medical students are able to see all types of patients and not the 'special' cases with which, by tradition, the teaching hospitals concern themselves. McKeown also discusses the administrative and financial implications of his sweeping proposals and makes appropriate recommendations.

This is the burden of one of the most important medical books to be written for many years. Its purpose is not how to improve medical services for their own sake, but how to treat disease; not how to improve the lot of doctors but how the general health of the community can be improved in all physical, mental and emotional aspects. It has relevance in underdeveloped as well as other countries.

The book may be dismissed as being impractical and even absurd. Others may fairly say that, in its concept of medical planning, it does not go far enough. In his proposal for a balanced hospital community, for example, McKeown pays little regard to the transport problems of getting patients to and from a few very large hospital groups; his proposals would need to be carefully worked out with town and country planning consultants, who should pay as much regard to rural as well as urban needs. Nor would he satisfy many that he is rightly aware of how a hospital should be designed to meet patients' true needs over the next thirty years; here much help would have to be obtained from specialists in method study, operational research and ergonomics. He would also have to exercise much more persuasion to convince many pregnant mothers—who have emotional as well as medical needs—that their babies should not be born at home. His difficulties with consultants and medical practitioners

and local authorities need not be underlined. However much these protest, and despite all the lamentations about cost, the proposals put forward in this most readable work are, in the end, largely bound to prevail. The inadequacies of modern medical services are so glaringly revealed in a book which is logically presented, skilfully written, and supported by periodic summaries to facilitate reading and understanding that it could well become a springboard to national remedial action.

T. H. HAWKINS

CINEMICROGRAPHY IN RESEARCH

Cinemicrography in Cell Biology

Edited by George G. Rose. Pp. 500. (New York and London: Academic Press Inc., Ltd., 1963.) 18.50 dollars; 132*s*. 6*d*.

IN the preface to *Cinemicrography in Cell Biology*, Dr. Rose states that, "Although not to be considered a general textbook of Cinemicrography, this volume brings together significant perspectives of an analytical approach. . .". However, while Dr. Rose has done a great service to every biologist who reads the book—for he has assembled a wide range of research papers linked by the common denominator, the use of cinematography in research—a great opportunity to produce a more comprehensive text, dealing fully with techniques, as well as results, has been lost.

The work is divided into three main sections, dealing respectively with 1, instrumentation; 2, tissues; 3, cells. The authors themselves are all respected workers in their own particular fields and their work discusses developments from many countries.

Part 1, read in conjunction with a good text on photomicrography, should enable any research worker to develop a time-lapse film laboratory, while avoiding some of the many pitfalls a beginner inevitably falls into. It is, however, interesting to note the number of times in the following papers that an author acknowledges the assistance of an established research film group which helped him with his instrumentation problems. There is little doubt that for effective use of film as a research tool, a sympathetic collaboration between film technologist and scientist is essential.

It is in parts 2 and 3 that an opportunity has been missed. Cinemicrography, in the biological field, deals essentially with the manipulation and photographic recording of living, growing tissues, observed during long periods of time: on the other hand, the technology of photomicrography deals only with manipulating the size and the optical/recording components of a system examining dead, or shortly to be dead, subjects. There is a wealth of literature on how to manipulate the photomicrographic systems in all their complex forms, but there is a serious dearth of comprehensive literature on the special methods required to maintain the growing cell or tissue, for observation and record, during long periods of time, while using film, and with the minimum of interference to the subject itself. The paper by Clay, Huff and Weathersby underlines this criticism when they say: "Such methods and techniques will be sufficiently discussed in other chapters of this volume, or in books devoted directly to tissue culture and photomicrography, to justify omitting description of them here". Unfortunately this material is not so easy to find—at all events collected between two covers—and a section devoted entirely to the effects of the filming process on various biological materials, on the methods of culture peculiar to the film technique, on the methods of constraint within the microscopic field, and on the methods and problems to be faced in analysing the photographic evidence would all have been most valuable.

However, in spite of possible omissions, *Cinemicrography in Cell Biology* will prove exceedingly valuable to any research worker; for it indicates the immense potential which film techniques in research can offer. It emphasizes the necessity for using film in parallel with the other methods of looking at any particular problem, and it underlines some of the instrumentation problems likely to be met when developing a cinematic technique. A wealth of references to papers discussing results could have been enhanced by a classified bibliography on methods, and the historical note found in the preface attributing the birth of microcinematography to an American scientific culture should be taken with a grain of salt.

On the cinemicrographic side this book is one of ideas, and further fields to explore, underlining ends rather than means. In fact, *Cinemicrography in Cell Biology* is a reference text which should be available in all research libraries.

E. LUCEY

AN ENCYCLOPAEDIA OF SPORE MORPHOLOGY

Morphologic Encyclopedia of Palynology

An International Collection of Definitions and Illustrations of Spores and Pollen. By G. O. W. Kremp. Pp. xiii+186+38 plates. (Tucson: The University of Arizona Press, 1965.) 15 dollars.

PALYNOLOGY—the science of pollen and spores—has developed, like many other things in the past twenty years, at a rate too great for comfort. A science which even a few years ago was unheard of even by many botanists has now two journals devoted to it, and palynological papers have intruded into more than two hundred journals in the allied fields of botany, geology, palaeontology and palaeobotany. With four to five papers on palynology appearing every week, and new species of fossil spores being discovered at a rate of a thousand a year, palynology is suffering some of the embarrassments of over-production. Many of the 'new' species of fossil spores reported more or less simultaneously from different parts of the world are evidently synonyms of one another. While consistent application of the International Code of Botanical Nomenclature will eventually resolve much of this, unfortunately no such code governs the plethora of terms used to describe the spores.

Morphologic Encyclopedia of Palynology sets out to elucidate the meaning of the 700 words coined expressly to describe the minute structure of spores—and the almost equal number of terms to which special palynological meaning has come to be attached. Prof. Kremp's book is in effect an exhaustive literature survey of this elaborate terminology: 1,280 terms are defined, their definitions quoted from original sources, and more than 800 are illustrated. In one sense, the book is an encyclopaedic dictionary, but no ultimate and definitive meaning of terms is given, nor is one usage advocated as being preferable to another. Prof. Kremp has been at pains not to impose his ideas on the reader: "it is not the object of this encyclopaedia to weed out 'incorrect definitions' and to tell other people what the author thinks 'correct definitions' should be". The "young worker in palynology . . . having before him the similar and related terms and definitions may make his own choices and judgements". A more assertive, Johnsonian interpretation of the prerogatives of a lexicographer might have helped to rid palynology of some of its superfluous terms.

This is the only serious negative criticism of the book; Prof. Kremp has done what he sets out to do with great care and painstaking thoroughness. He has produced an essential reference source for workers not only in palynology but in the neighbouring fields into which this vigorous science is overflowing.

W. G. CHALONER

THE NEW CENTER FOR THE LIFE SCIENCES AT THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

By Prof. IRWIN W. SIZER

Head, Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts

On December 2 and 3, 1965, an international symposium on the "Life Sciences" was held at the Massachusetts Institute of Technology on the occasion of the dedication of the Uncas A. and Helen F. Whitaker Building. This, together with the contiguous Dorrance Building (and certain ancillary laboratories), houses the new Center for the Life Sciences which comprises the Departments of Biology and Nutrition and Food Science. The Center provides an extensive teaching programme for undergraduate, graduate and post-doctoral students. The latter include a number of medical doctors who are being trained for research in basic medical sciences. In addition, the Center is devoted to research in specialized areas of the life sciences such as molecular biology, biophysics, biochemistry, microbiology, physiology, and developmental biology in the Department of Biology, and human and animal nutrition, food science and technology in the Department of Nutrition and Food Science. In both Departments, special emphasis is given to the application of the physical sciences and engineering to education and research in the life sciences.

The new 6-million dollar Whitaker Building (Fig. 1) has eight stories above ground and two below, providing 134,000 gross square feet of additional space for the Departments of Biology and of Nutrition and Food Science. It has a poured-in-place reinforced concrete frame, with metal and glass exterior curtain walls, and is air-conditioned throughout. It was financed in part by the National Institutes of Health, by the Second Century Fund of the Massachusetts Institute of Technology, and by a generous grant from Uncas and Helen Whitaker. Mr. Whitaker is a graduate of the Massachusetts Institute of Technology and is now a member of its Corporation. He is also chairman of the Board and chief executive officer of AMP, Inc. (formerly Aircraft-Marine Products). For many years he and Mrs. Whitaker have been interested in the encouragement of research and teaching in medicine and the life sciences in the United States.

The international symposium on the "Life Sciences", under the general chairmanship of Dr. Jerome B. Wiesner, dean of the School of Science, was opened by Dr. Julius A. Stratton, president of the Massachusetts Institute of Technology. In the first session, "Molecular Structure and the Functional Organization of Cellular Constituents", of which Prof. Salvador E. Luria, Sedgwick professor of biology at the Massachusetts Institute of Technology, was in the chair, major advances in translating molecular structure of nucleic acids into functional specificities of proteins and the relation of macromolecules to cellular structures were reviewed. Speakers in this programme included: Dr. F. H. C. Crick, Medical Research Council Laboratory for Molecular Biology (Cambridge); Prof. Daniel E. Koshland, jun., professor of biochemistry, University of California (Berkeley); Prof. Tracy M. Sonne-

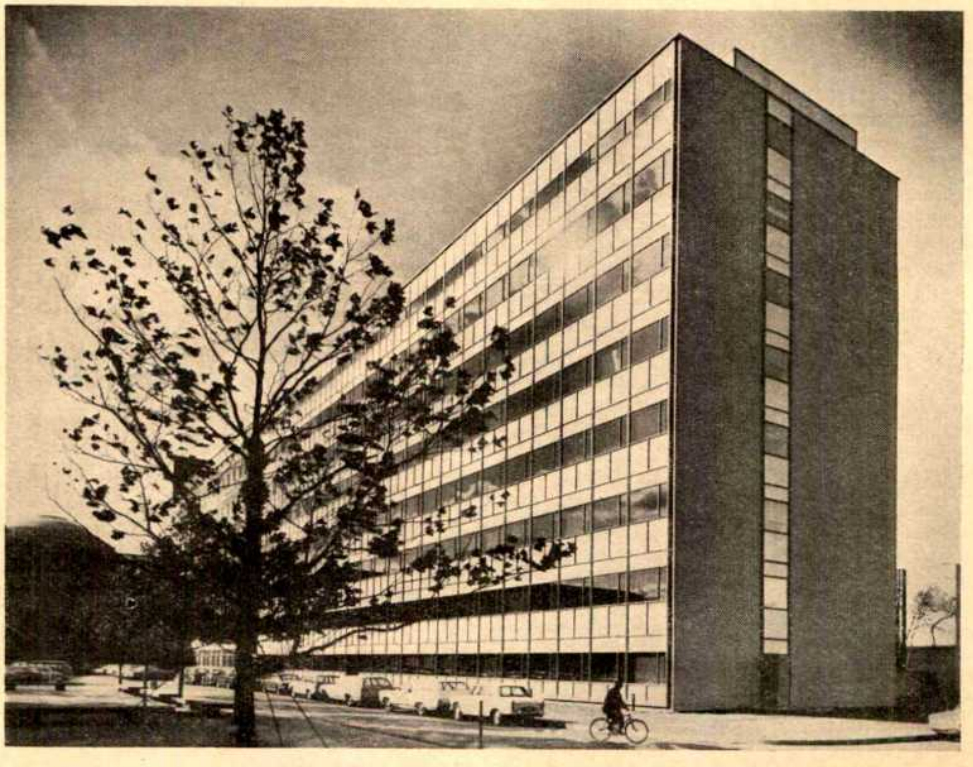

Fig. 1. Center for the Life Sciences, Massachusetts Institute of Technology; the Uncas A. and Helen F. Whitaker Building is in the foreground

born, distinguished service professor of zoology, University of Indiana.

The second session, arranged by Prof. Patrick D. Wall, professor of physiology at the Massachusetts Institute of Technology, was devoted to "Adaptation and Functional Co-ordination" and included a consideration of sensory mechanisms, the central analysis of sensory patterns and the production and control of behaviour patterns which adapt the animal to its environment. Participants in this session were: Prof. J. Z. Young, professor of anatomy, University College (London); Prof. Vincent G. Dethier, professor of zoology, University of Pennsylvania; Prof. Theodore H. Bullock, professor of zoology, University of California (Los Angeles).

In the third session, "The Future of Man and the Life Sciences", chaired by Prof. Samuel A. Goldblith, professor of food science at the Massachusetts Institute of Technology, the relevance of recent advances in basic and applied biology to the problems of over-population and man's food supply were discussed. Speakers in this session were: Prof. Ritchie Calder, Montague Burton professor of international relations, University of Edinburgh; Dr. Clement L. Markert, chairman of the Department of Biology, Yale University; Prof. Roger Revelle, Richard Saltonstall professor of population policy and director of the Center for Population Studies, Harvard University.

The theme of the third session was continued in an evening address on "Molecular Medicine" by Dr. A. Baird Hastings, head of the Laboratory of Metabolic Research, Scripps Clinic and Research Foundation, and in the dedication programme on "The Life Sciences and Society" by Dr. George W. Beadle, president of the University of Chicago.

The educational programme in the Center for the Life Sciences is devoted primarily to training 125 undergraduate majors and 175 graduate students. In addition, there are about 130 postdoctoral Fellows, many of them medical investigators who are receiving special training in research. Courses leading to a Ph.D. degree are offered in biophysics, biochemistry, microbiology, physiology, biology, nutrition, food science, biochemical engineering, and bioengineering. These teaching programmes are administered by a faculty of fifty professors in the life sciences.

Closely associated with the Center for Life Sciences is the new Clinical Research Center with its modern hospital facilities available to faculty who wish to carry out research using patients or student volunteers. Also closely allied with life sciences are the Communications Center and the Neurosciences Center, both of which have extensive programmes related to the nervous system. Research in the life sciences is also being carried out in most of the departments at the Massachusetts Institute of Technology, and indeed 25 per cent of all the research projects in the Institute are devoted to the life sciences. The scope of these projects is extremely broad, but in general they involve the application of science and technology to biological problems. Such equipment as nuclear reactors, giant computers, electron microscopes, cyclotrons and high-voltage X-ray generators, find many uses in research in the life sciences. The use of such facilities requires close collaboration between scientists and engineers throughout the Massachusetts Institute of Technology.

Biology has been taught at the Massachusetts Institute of Technology from the time of its foundation (1861) and was given emphasis in 1871 when a new course in natural history was established "whose ulterior objective is the special pursuit of geology, mineralogy, botany, zoology, or to prepare for medicine, pharmacy, or rural economy". In the years from 1883 until 1921, under the leadership of Prof. William Sedgwick, the Institute won renown as a centre for the life sciences relating to microbiology and public health. Sedgwick was the first to demonstrate that infectious disease could be caused by pollution of water supplies and as a result of this research became known as the "Father of American epidemiology". Work on water supplies soon led to bacteriological investigations of foods which, under Dean Samuel C. Prescott, led to the development of food sterilization and the canning industry in the United States. Research on food and nutrition at the Institute became so important that a graduate Department of Nutrition and Food Science was separated from the Department of Biology in 1942, making it possible for the latter Department to concentrate its efforts on the utilization of the physical sciences in basic research and teaching in the biological sciences. About half the undergraduates who major in the life sciences at the Massachusetts Institute of Technology are preparing for medical school and half for graduate school. The establishment of the new Center for the Life Sciences enables the two Departments to co-operate closely in teaching and research.

The Department of Nutrition and Food Science, under the leadership of Prof. Nevin S. Scrimshaw, will emphasize in its teaching and research programme such topics as clinical and biochemical nutrition, veterinary pathology, oral science, toxicology, and food preservation and processing as well as food chemistry. The Department of Biology, with Prof. Irwin W. Sizer as its head, will offer educational and research programmes which will concentrate on molecular biology, biophysics, cell physiology, neurology, biochemistry, microbiology, developmental biology, and bioengineering. The programmes of the two Departments plus the contribution of other departments and centres should make it possible for the Massachusetts Institute of Technology to play a leading part in the development of the life sciences in the world during the next decade.

NOTATION FOR GENETIC FACTORS OF HUMAN IMMUNOGLOBULINS*

IN a previous memorandum stating recommendations for a uniform notation for human immunoglobulins[1] it was considered advisable that analogous recommendations be made in the future for genes, genotypes and allotypes. In that memorandum, classes of human immunoglobulins which are common to all normal individuals of a given species were considered. These classes of immunoglobulins can be distinguished from each other by a number of means including their antigenic specificity (isotypic specificity).

Another kind of classification, which is at present based on serological typing, distinguishes variants which occur among proteins of the foregoing classes. The corresponding determinants, which are present in some groups of individuals within the species, define antigenic specificities which in animals are commonly termed 'allotypic specificities' and in man 'factors'. Many of these antigenic specificities determine genetic polymorphisms in the different races of man and other animals.

The genetic factors of human immunoglobulins are at present identified by serological tests which measure the inhibition by the test material of the agglutination of erythrocytes pre-coated with incomplete antibody. The

* This memorandum was drafted by us following discussions held during the meeting of the World Health Organization Scientific Group on Genes, Genotypes and Allotypes of Immunoglobulins, held during May 31–June 5, 1965, in Geneva.

agglutinating antibodies occur in selected sera from patients with rheumatoid arthritis or from normal subjects. The incomplete coating antibodies are usually IgG immunoglobulin molecules and the agglutinating reagents are usually IgM molecules. The whole serum, an isolated immunoglobulin, or an immunoglobulin sub-unit may be used in such an inhibition test.

The term 'factor' defines a particular property of certain immunoglobulins which enables them to be identified by a given set of reagents, but it should be noted that the characterization of factors by these means does not preclude the possibility of a cross-reaction.

Family studies have shown that the factors involved are inherited according to Mendelian principles. Two series of factors controlled by independent genetic systems are known; one (the Gm system) is associated with the heavy polypeptide chain of some IgG molecules, and the other (the Inv system) is associated with light polypeptide chains of immunoglobulin molecules.

The nomenclature at present in use is based on serological tests, with genetical analysis providing linkage group information. In higher organisms, the term locus (and the corresponding terminology for genes and genotypes) may be ambiguously used for indicating either a complex chromosomal region or a structural gene, and owing to the nature of serological analysis a one-to-one correspondence between one factor and one gene or one region of a gene cannot be inferred at the present time. For these reasons, the term 'system' is used here for a unit of closely linked genetic information which cannot be separated into sub-units at the level of resolution allowed by formal human genetics.

A new notation should provide a symbol which suggests the relation of the system to the structure it influences, which does not go beyond established fact and which is sufficiently flexible to meet future needs. It should relate to prior terminology for the same system if at all possible, and provide for different systems a series of symbols which differ from each other by at least two letters when practicable. The following recommendations have been designed to meet these requirements so far as possible.

Notation for the factors of the Gm and Inv systems. At the present time, the accumulated information is insufficient to permit precise correlation of the genetic loci for the human immunoglobulins with the structures they influence. Consequently, it seems advisable at this time to retain the present symbols Gm and Inv to describe the two systems currently recognized. For these systems, particularly at the Gm locus, an ever-increasing complexity has been developing in recent years. To avoid these complexities and the implication of possibly false relationships, we recommend a non-committal, flexible numerical notation, similar to that suggested for the *Salmonella* antigens, Rh blood groups, and histocompatibility antigens in the mouse.

The assignment of numbers to the already known Gm and Inv factors has been done using the principles outlined below and considering also the order of their discovery and the known relationships of the Gm factors to the sub-groups of the polypeptide chain of IgG.

Table 1. Notation for the Factors at the Gm Locus*

b^5	14

* A number has not been assigned to Gm (D) because it has been found to be an artefact and not a Gm factor.

Table 2. Notation for the Factors at the Inv Locus

Original	New
l (lower-case L)	1
a	2
b	3

Either of two methods is suitable for recording the phenotype of an individual.

(*a*) Record the result obtained with each set of reagents: for example, Gm(1,−2,3,4,5); Inv.(1,−2,3). Punctuation includes commas between the reactions with each set of reagents. This would mean that the sample was tested with reagents which correspond to the factors Gm(1), Gm(2), Gm(3), Gm(4), and Gm(5) and Inv(1), Inv(2), and Inv(3); and that it was positive with the test systems for Gm(1), Gm(3), Gm(4), and Gm(5), and negative for Gm(2); and positive for Inv(1) and (3), and negative for Inv(2).

(*b*) Record only the positive results: for example, Gm(1,3,4,5); Inv.(1,3). In this case, the factors tested cannot be determined from the recorded phenotype and reference must be made to the list of reagents used for this information.

It is recognized that studies with several sets of reagents of Gm factors 7–14 inclusive have not yet been extensively published. Nor is the closeness of the relationship between Gm(3) and Gm(4) precisely known at the present time. These factors have nevertheless been assigned separate numbers here. Further decisions in the form of deletions of some numbers are foreseen.

The phenotypes of isolated discrete (for example, myeloma) proteins may be recorded on the same basis as whole serum and by adding the symbol for the immunoglobulin sub-type if known. For example: phenotypes γ_2b : Gm(1,2); or γWe : Gm(1,2); κ : Inv(1); etc.

Notation for genes. Symbols for genes should be underlined when typed and italicized when printed. The factors determined by the gene should be indicated by superscript digits.

It is understood that the assignment of a genotype to a phenotype can be done only after genetic analysis, that is, the observation of family segregation. Assignment of the 'most probable' genotype in the absence of family data should be clearly indicated.

Table 3. Examples

Phenotype*	Population	Most probable genotype
Gm(1,5)	Caucasoid	Gm^1/Gm^5
Gm(1,5)	Negroid	$Gm^{1,5}/Gm^{1,5}$
Gm(1,2)	Caucasoid or Mongoloid	$Gm^{1,2}/Gm^{1,2}$ or $Gm^{1,2}/Gm^1$

* All samples were tested for Gm(1), Gm(2) and Gm(5).

It should be emphasized that findings in other immunological systems indicate that serological specificities may appear in the phenotype which may not be represented in the genotype (that is, specificities resulting from interaction of different genes). Although such specificities have not yet been found in the human immunoglobulins, the proposed system of nomenclature may be used to record them.

The use of genetic symbols containing several numbers is a convenient notation to describe the inheritance of complex patterns of serological reactions (phenogroups). The symbols do not imply that regions corresponding to the individual numbers do or do not exist in the relevant genes. For example, a gene $Gm^{1,2}$ does not necessarily have part of its structure determining factor 1 and a different part determining factor 2.

Notation for new systems. It is possible that new factors in addition to those at present known will be discovered and shown to be inherited independently of any of the known systems. If this occurs it seems advisable to relate the system symbol to the immunoglobulins and to the appropriate polypeptide chain and to re-name the Gm and Inv systems at present established so that their

symbols reflect the structural units they control. In this event, it is suggested that the symbol 'I' be used as the initial letter in the description of all the loci for the immunoglobulins.

Notation for new factors. There is no wish to restrict the freedom of investigators to publish data in any way they desire. On the other hand, the usefulness of the proposed system of notation will be seriously jeopardized if numerical symbols are added to the present list in an unco-ordinated way. For these reasons, the following recommendations are made:

(*a*) If the serological and family data are insufficient to meet the criteria for recognition of new factors set out below, either because of insufficient quantity of the reagent or because the frequency of the factor in the population precludes definitive family studies, it is recommended that the author give the new factor a provisional name using a two-letter abbreviation derived from town name, name of patient, etc. This should be preceded by the non-specific generic term I, rather than a specific system symbol, for example, I(pr) and I(−pr) for the phenotypes.

(*b*) If the factor which has not yet been assigned a number is known to be part of the Gm or Inv systems, it can be indicated in the parenthesis after the numbered factors, for example: Gm(1, −2,3,4,5,pr) or Gm(1,3,4,5,pr).

(*c*) If the author believes that the criteria are fulfilled and that the linkage relations have been established, the use of a number instead of the provisional name is warranted. To avoid duplicate use of the same number a request for a number should be sent to the World Health Organization International Reference Centre for Genetic Factors of Human Immunoglobulins, addressed to Dr. C. Ropartz, Directeur, Centre départemental de Transfusion sanguine et de Génétique humaine, 609, Chemin de la Bretèque, 76–Bois-Guillaume, France.

(*d*) If the factor is shown to belong to one of the already known linkage groups (systems), it would be assigned the next available number of that group, for example, Inv(4).

(*e*) If the factor is shown to belong to a different system, it would be given the number 1. If it is located on a particular immunoglobulin class, the system symbol could be chosen according to the suggestions made here. In choosing the system symbol for a factor not localized on one particular class of immunoglobulins, transposition of the provisional letter into the system symbol might be useful. The phenotype I(pr) would in this instance be changed to IPr(1).

None of these suggestions should be taken to imply any formal control over the future use of numbers to describe factors inherited in the immunoglobulins. The sole intention is to avoid duplication of numbers or their use for poorly defined factors, and to assist in the rapid inclusion of reported factors into the proposed system of notation. Circulation of data relevant to their identification to other investigators would be helpful in this respect.

Criteria for recognition of new factors. To establish that a test system detects a 'new' factor, it is recommended that the following conditions be fulfilled:

(*a*) The reaction system employed should show complete reproducibility. With the present haemagglutination-inhibition technique, the difference between 'inhibiting' and 'non-inhibiting' normal sera from the same population should be three tubes or higher in a twofold dilution test system.

(*b*) Since antisera may contain mixtures of antibodies of different specificities, steps should be taken to show that the observed 'new' reaction patterns are not due to an obvious mixture of antibodies of previously known specificities. (Absorption experiments using cells coated with selected antibodies, inhibition tests with purified myeloma proteins, and tests for consistency using cells coated with antibodies from different persons may give information concerning these matters.)

(*c*) It is essential to specify all reagents used in any study because, (1) two reagents (antiglobulin and a cell coat) are necessary to define a factor; (2) the same coated cells in some cases may be used for defining more than one factor; and (3) the antiglobulin from one person may be used with different cell coats to define more than one factor (see Table 4).

Table 4. ANTIGLOBULIN FROM ONE PERSON USED WITH DIFFERENT CELL COATS TO DEFINE MORE THAN ONE FACTOR

Factor	Anti-globulin	Dilution	Cell coat	Dilution
Gm(5)	Dr.*	1/8	Anti-D V.S.*	1/5
Gm(13)	Th.*	1/8	Anti-D V.S.*	1/5
Gm(6)	Bomb.*	1/32	Anti-D Warren*	1/10
Gm(5)	Bomb.*	1/32	Anti-D Berg*	1/10

* Identification of reagent.

(*d*) Enough family data should be obtained to establish the pattern of inheritance of the new factor.

(*e*) Tests with isolated immunoglobulins from positive and negative sera should be performed to show that the new factor is associated with immunoglobulins. Tests with agammaglobulinaemic sera might also be useful.

(*f*) The reactions observed with the new set of reagents should be different in at least one race from those of any previously described set of reagents. It is suggested that a useful standard for deciding that the new factor differs from known factors is a χ^2 test of the comparisons of the reaction with different reagent sets, giving values with a $P \leqslant 0{\cdot}02$. However, one clearly established and inherited difference, confirmed in several laboratories, may be acceptable as evidence for a new factor.

Reference panel of sera. In order to maintain uniformity in reagent sets used to detect established differences between the immunoglobulins of different individuals, the specificities of the reagent sets should be defined by their reactions with a reference panel of normal human sera. It is hoped that such a panel will be made available through the World Health Organization International Reference Centre for Genetic Factors of Human Immunoglobulins.

EXISTENCE OF A SIGNIFICANT LATITUDINAL VARIATION IN DENSITY FROM 200 TO 800 KILOMETRES

By A. D. ANDERSON
Lockheed Palo Alto Research Laboratory, Palo Alto, California

USING satellite orbital decay data, the effect of longitude on density, known as the diurnal (time-of-day) effect, has been well established. With these data, until recently, it has not been possible to prove definitely the existence of any significant latitudinal variation in density. Different investigators have reported slight latitudinal density variations, but the various findings are not in agreement[1–3]. Now, the existence of an appreciable latitudinal density gradient has been demonstrated by May[4], who analysed data from the *Discoverer* series of satellites, the altitudes of which ranged between 190 and 260 km and perigees from 80° S to 80° N. He concluded that the air density at a fixed height is a function of latitude and is about 30 per cent smaller at the poles than at the equator. May's conclusion is corroborated by the following independent analysis performed by me that is based on a different method of deriving the behaviour of density with latitude.

The upper-atmosphere density ρ, in g cm^{-3}, can be represented by:

$$\rho = K'' S'^{N} \qquad (1)$$

where S' is a daily indicator of the extreme ultra-violet radiation of the Sun, expressed in units of the 10·7-cm flux S (10^{-22} W m^{-2} (c/s)$^{-1}$). These radio astronomy units will be understood to always apply to S' in this article. K'' and N are constants for a given altitude h and local time t. They are presented in tables[5] for selected altitudes from 200 to 800 km and every hour, where the local time t = 12 h (local noon) corresponds to a zero angular difference between the right ascension of the local meridian and the right ascension of the Sun; t = 24 h (local midnight) corresponds to a difference of 180°.

Using equation (1) together with tables, the density and its variations can be readily calculated as a function of S'. The index S', in turn, is derived from S and drag data for satellite 1958 α, by correcting for the amount by which S fails to predict exactly the satellite drag when it is substituted in equation (1) (ref. 5). Thus, S' represents the total extreme ultra-violet radiation from the Sun, estimated from satellite orbital decay data for 1958 α by assuming that its drag variations result only from changes in the extreme ultra-violet radiation that affect atmospheric density.

Fig. 1 exhibits a curve of S', based on monthly averages from 1958 to 1962. The curve for S is displayed for comparison. The S' curve is noticeably different from the S curve. Two marked features appearing in Fig. 1 are (*a* the relative minimum values of S' for either June or July during the 5 years from 1958 to 1962, and (*b*) the semi-annual variation exhibited in the S' curve (but not the S curve) in 1961 and 1962, with maxima around the equinoxes and minima around the solstices. The most likely explanation for the semi-annual variation in S' in 1961 and 1962 is that the S' values reflect a latitude variation in density. Thus, S', taken as a measure of the daily output of extreme ultra-violet radiation from the Sun, is calculated by assuming that satellite drag (density) changes are due only to variations in the extreme ultra-violet radiation. While S' is independent of changes in longitude of the perigee of 1958 α, the method of calculating S' did not take into account changes in the latitude of perigee. Since the amount of extreme ultra-violet radiation intercepted by the Earth's upper atmosphere should vary with latitude, except in the summer, when the daily insolation is nearly independent of latitude, therefore S' should vary with latitude also.

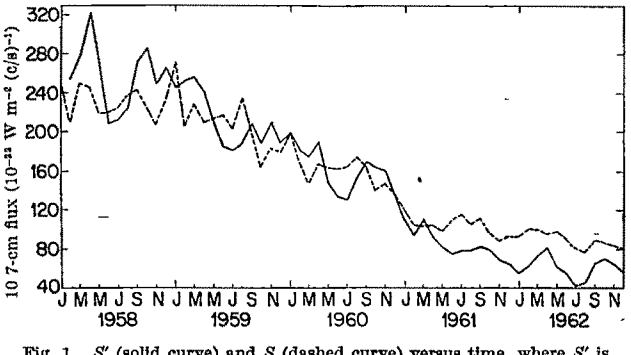

Fig. 1. S' (solid curve) and S (dashed curve) versus time, where S' is derived from satellite 1958 α by comparing calculated rates of orbital decay with observed values and S is the 10·7-cm solar flux

The diurnal effect is one in which the density varies with local time or the longitude difference between the given location and the sub-solar point. This indicates that any analysis of the density variation with latitude should take into consideration the latitude variation of the sub-solar point. The density at any point at a given altitude above a given geographical location on Earth should vary with the difference between the latitude of this location and the latitude of the sub-solar point, which changes in the course of the seasons. If, instead of having a fixed point above the Earth, satellite perigee is used, which also has latitude variations, then the density should vary with the difference between the latitude of perigee and the latitude of the sub-solar point. Since density is represented as a function of S' (equation 1), the nature of the density variation with latitude can be determined by analysing how S' varies with the combined movement of satellite 1958 α and the Sun north and south of the equator.

Curve *a*, Fig. 2, shows how the perigee for 1958 α varies with latitude in 1962. Positive latitude denotes perigee north of the equator, while negative latitude is for the perigee south of the equator. The same convention is followed for the latitude of the sub-solar point (declination of the Sun). Curve *b*, Fig. 2, presents the variation of the declination of the Sun during the year. Curve *c*, Fig. 2, the result of subtracting curve *b* from curve *a*, illustrates how the angular distance of the perigee north or south of the sub-solar point, θ', varies in 1962. The perigee reaches the maximum distance south of the sub-solar point ($\theta' = -56°$) when it is farthest south of the equator near the end of June. Likewise, the perigee reaches the maximum distance north of the sub-solar point ($\theta = +56°$) when it is farthest north of the equator in both December and January. Curve *c*, Fig. 2, is typical for other years from 1958 to 1961; the perigee reaches the maximum distance south of the sub-solar point near the summer solstice in the northern hemisphere (June or July) and the maximum distance north near the winter solstice (December or January).

Fig. 3 gives curves of the absolute value of θ' (curve *a*) and S' (curve *b*) for 1961 and 1962, where the S' data points are plotted on a scale increasing downwards. The S' data points are monthly averages corrected for the

solar cycle trend by normalizing them to January 1962. A comparison between the two smooth curves a and b, drawn to the data point averages of θ' and S', shows that S' inclines to be a maximum at the sub-solar point, decreasing both north and south of it, thus indicating a definite relationship. This preliminary analysis supports the assumption that S' is affected by latitude variations in the perigee of satellite 1958 α. In the following paragraphs, S' values are analysed in detail by a method devised to uncover the effect of latitude. Since seasonal effects are also indicated to be important, the method used treats the S' data by season for both the northern and southern hemisphere.

The S' values for 1961 and 1962 were calculated using satellite orbital decay data of Jacchia and Slowey[6], and Izsak[7,8]. Since the decay values (P) were available usually only every fourth day, the calculated S' values were plotted on an S' versus time (days) graph, a smooth curve was drawn through the data points, and daily S' values were derived by interpolation. These daily values of S' were corrected for two effects: one is the long-term (solar cycle) variation in the output of extreme ultra-violet radiation by the Sun; the other is the short-term variation in extreme ultra-violet radiation due to the rotation of the Sun. For the former, Fig. 1 discloses that the long-term trend of S' is down from 1958 to 1962. The daily S' values for 1961 and 1962 were corrected for this trend by normalizing them to January 1962 by means of a tendency curve fitted to 6-month average S' values. The following procedure was adopted to minimize the effect of the 27-day periodicity in S': the daily S' values for 1961 and 1962, normalized to January 1962, were grouped according to 10-degree intervals of θ', by season, where May, June and July, the three consecutive months corresponding to the maximum positive declination of the Sun, are taken as northern hemisphere summer (the other seasons follow according to the hemisphere). Then average S' values were computed. These are displayed in Table 1 together with the number of cases for each average. Averages were not included in Table 1 if, (a) the number of cases was less than 10; (b) an average for 1961 differed by more than 20 per cent from that for 1962 for the same season and θ' interval; (c) an average for a given season deviated by more than 10 per cent from the average above or below it in Table 1. These criteria ensured that the S' averages in Table 1 were not unduly affected by an unequal distribution of daily S' values, favouring either high or low values, within a 27-day period. More accurate trends with latitude and season could be established by the elimination of inconsistent or doubtful averages. Another source of error in the S' averages could arise from errors in the satellite orbital decay values. The tracking data used to derive the P values are sporadic and frequently inaccurate. Jacchia and Slowey[9] have described one type of error in P for 1958 α, consisting of drag oscillations of period of approximately 3·5 days and amplitudes that reach 40 per cent. By averaging over a season it should be possible to eliminate these shorter period errors.

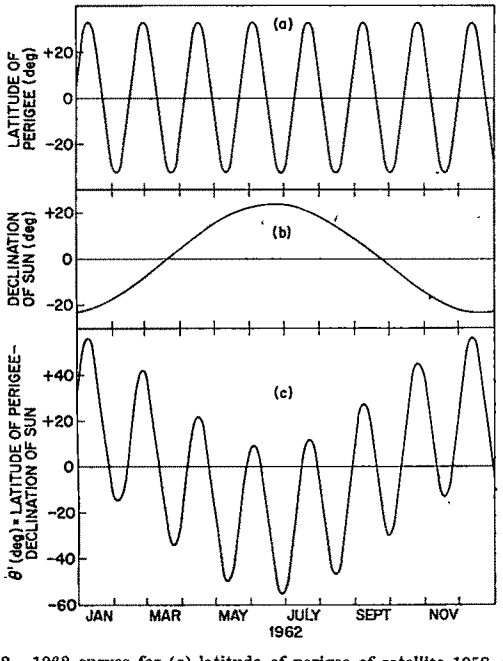

Fig. 2. 1962 curves for (a) latitude of perigee of satellite 1958 α; (b) declination of Sun (latitude of sub-solar point), (c) latitude of perigee of 1958 α minus declination of Sun (curve a–curve b)

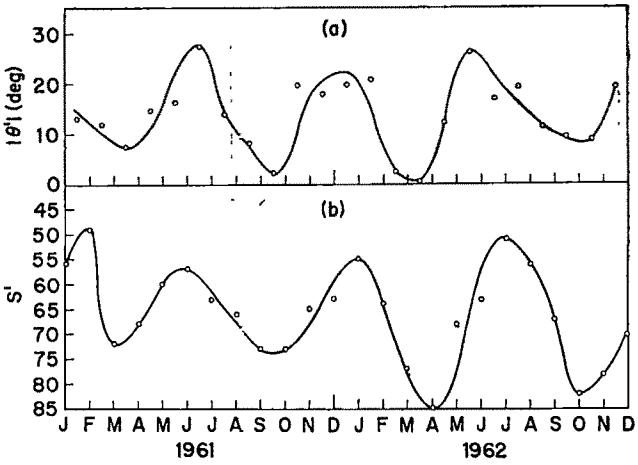

Fig. 3. 1961 and 1962 curves for (a) the absolute angular distance north or south of the sub-solar point, [θ'], (b) S'. Note that the S' scale increases downwards

The S' averages in Table 1 were plotted on an S' versus θ' graph, in Fig. 4, by placing the S' data points at the mid-points of the respective θ' intervals. The data points for the respective 3-month seasons were connected with solid straight-line segments. The resulting solid curves all indicate meaningful trends with latitude. Their average slope is in good agreement with May's Fig. 2 (ref. 4), which is a plot of density against latitude for *Discoverer* satellites, except for the northern hemisphere autumn curve. This anomaly will be discussed later. It should be pointed out that May's plot extends over the period from August 1959 to December 1960, while the data points in Fig. 2 of this article are for 1961 and 1962. The average value of the S' data points in Fig. 4 on the solid curve

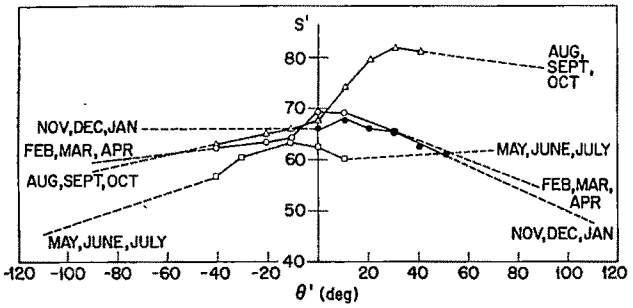

Fig. 4. S' versus θ', the angular distance north or south of the sub-solar point, for the four seasons in 1961–1962. The solid curves connect S' data points; the dashed curves are extrapolations to the poles based on astronomical consequences of upper-atmosphere heating by solar extreme ultra-violet radiation. ●, Nov., Dec., Jan.; ○, Feb., Mar., Apr.; □, May, June, July; △, Aug., Sept., Oct.

for May, June and July (corresponding to geographical latitudes 20° S. to 30° N.) is 60·6. This value is 6·0 per cent less than the average of 64·5 for the points on the November, December and January curve for the same latitude band. There should be 6·5 per cent less extreme ultra-violet radiation intercepted by the Earth's upper atmosphere in July than January because the Earth is farther from the Sun in July. A calculation, based on taking an average Earth–Sun distance for 3-month intervals, indicates that the average S' for May, June and July should be 5·3 per cent less than the average for November, December and January due only to this distance variation. This value of 5·3 per cent compares well enough with the 6·0 per cent value already given to suggest that the difference between the two solid curves can be explained on the basis of the varying Earth–Sun distance alone.

The average latitude of the sub-solar point, $\bar{\theta}_s$, is close enough to the equator ($\theta_s \simeq 0$) during the spring and autumn so that the average geometric latitude, $\bar{\theta}$ (where $\theta = \theta' + \theta_s$), is approximately equal to the average θ' or $\bar{\theta} \simeq \bar{\theta}'$. Also, $\bar{\theta} \simeq \bar{\theta}' - 20°$ for the winter in the respective hemisphere, and $\bar{\theta} \simeq \bar{\theta}' + 20°$ for the summer. Therefore, the north pole is at $\bar{\theta}' \simeq 110°$ during the northern hemisphere winter. In Fig. 4, the solid curve for this season is extrapolated to the north pole by a dashed straight line, continuing the trend manifested by the last two data points. The southern hemisphere winter (May, June and July) curve is linearly extrapolated by drawing a dashed line between the S' value for the south pole (taken to be 5·3 per cent less than the north pole winter value) and the last data point. To account for the fact that during the summer the daily exposure to the extreme ultra-violet radiation of the Sun (represented by S') at the pole is nearly the same as at the equator, the southern hemisphere summer curve is extrapolated to the south pole by drawing a dashed straight line between the last data point and an S' value at the south pole equal to the value at the equator. The same procedure was followed in extrapolating the May, June and July curve to the north pole. The remaining curves for spring and autumn were linearly extrapolated to the poles by drawing dashed lines to continue the trends denoted by the last two data points at the ends of the solid curves.

The S' data points in Fig. 4 substantiate the picture of upper-atmosphere seasons as derived from astronomical considerations, except for the northern hemisphere autumn season. The rise to high S' values from the equator to mid-latitudes, with maximum at 30°–40° N., exhibited by the August, September and October curve is quite unusual. This unexpected feature is fully supported by the S' data, both in 1961 and 1962. Apparently, there is additional heating, not caused by solar extreme ultra-violet radiation, that affects the northern hemisphere at mid-latitudes near the autumn equinox. Heating associated with geomagnetic activity is one possibility. Jacchia[10] has demonstrated that there is a conspicuous drag effect on satellites associated with major magnetic storms. Dessler[11] has proposed one mechanism for such heating involving hydromagnetic waves, but it is difficult to find a physical explanation for asymmetric heating with regard to both the equinoxes and the two hemispheres. The curves of Fig. 4 will not be representative of gradients in the auroral zones during major magnetic storms. Jacchia and Slowey[12] have indicated from the analysis of the atmospheric drag affecting the *Injun* 3 satellite that the heating accompanying geomagnetic perturbations in the auroral zones is 4 or 5 times greater than the heating experienced during these perturbations in low latitudes. However, the model embodied in Fig. 4, based entirely on variations of the extreme ultra-violet radiation, best explains the S' variations in Fig. 1.

The following qualitative description of the upper-atmosphere global density distribution is a consequence of Fig. 4 and equation (1): The density at a given altitude decreases from the equator to the poles, except for the summer, where there is little or no gradient, and the autumn in the northern hemisphere, where the density increases from the equator to 30°–40° N. The season with the lowest density is winter. The winter in the southern hemisphere is less dense than the same season in the northern hemisphere because the Earth is farther from the Sun during May, June and July. Therefore, since the minimum density in each hemisphere occurs over the respective pole during the winter, the absolute minimum density over the Earth is at the south pole during this season. Latitude 30°–40° N. has the maximum density (autumn season). The autumn and spring density gradients are intermediate with respect to those of summer and winter, except for the autumn season in the northern hemisphere the gradient of which is anomalous and unexplained. It will be shown that when the diurnal (longitude) effect on the density is taken into account, the foregoing picture is modified by the introduction of a marked latitude gradient above 400 km in the polar regions for all seasons.

Table 2 presents S' values by season and geometric latitude θ from 90° S. to 90° N., as selected from the curves of Fig. 4 by using the appropriate conversions between $\bar{\theta}'$ and $\bar{\theta}$. Displayed also are the ratios $S'(\theta)/S'(0)$, representing the value of S' at latitude θ relative to its value at the equator ($\theta = 0$), both for the same local time. Since $N = 1$ in equation (1) at 200 km, these ratios express the relative density variation with latitude for a given season at this altitude. For example, in winter the densities at both poles are 27 per cent lower than at the equator for the same local time. Later on, it will be clear that Table 2 is most accurate for the early morning hours, 5–7 h local time. Fig. 5, drawn from the $S'(\theta)/S'(0)$ values in Table 2, gives the relative S' (density at 200 km) variation with latitude in the form of curves for each of the four seasons. The hemispheric parts of the curves correspond-

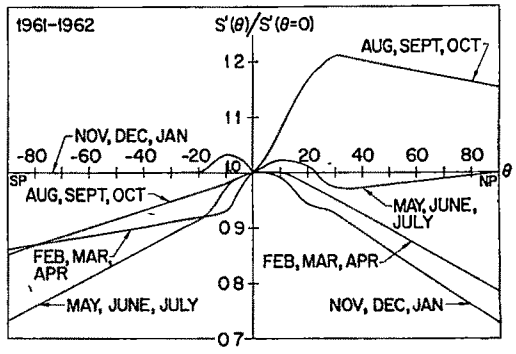

Fig. 5. $S'(\theta)/S'(\theta = 0)$ versus θ (latitude) for the four seasons in 1961–1962 from pole to pole, where $S'(\theta)$ is the value of S' at latitude θ, $S'(\theta = 0)$ is the S' value at the equator, NP is the north pole, and SP is the south pole. These curves represent the relative S' (or density at 200 km) variation with respect to the equator

ing to winter, summer and spring are roughly symmetric with respect to the equator.

The relative density variation with latitude can be calculated for a higher altitude up to 800 km by using the S' values from Table 2 together with the K'' and N values (equation 1) corresponding to the selected altitude and local times in the following equation:

$$\rho(\theta)/\rho(0) = K''(\theta)S'(\theta)^{N(\theta)}/K''(0)S'(0)^{N(0)} \qquad (2)$$

where $\rho(\theta)$ and $S'(\theta)$ are the density and S' at latitude θ, respectively, and $\rho(0)$ and $S'(0)$ are the density and S' at the equator, respectively. The local times at θ and the equator are accounted for through the K'' and N values corresponding to these times, namely, $K''(\theta)$, $N(\theta)$ and $K''(0)$, $N(0)$. Normally the same local time will be used for θ and the equator, but for calculations involving the polar regions, different times may have to be used. There should be only minor diurnal fluctuations in density at the poles during the spring or autumn seasons. During the summer there should be practically no diurnal variation, since the altitude of the Sun, which is never far above the horizon, and the extreme ultra-violet radiation do not change significantly with time of day. During the winter, of course, there is no Sun. Therefore, a reasonable estimate of the time for relative density calculations involving the pole is $t = 5$ h for the winter, $t = 6$ h (sunrise) for spring and autumn, and $t = 7$ h for summer.

Table 3 illustrates how the hemispheric latitudinal gradient can change with altitude for the various seasons. The ratios of the polar to equatorial density, $\rho(N)/\rho(0)$ and $\rho(S)/\rho(0)$, are given at 200, 400, 600, and 800 km and the four seasons, where $\rho(N)$ and $\rho(S)$ are the densities at the north and south pole, respectively, and $\rho(0)$ is the density at the equator. The local time t is taken to be 6 h for convenience; hence, the ratios are most representative for the spring and autumn seasons. When the ratios are less than one at 200 km, they decrease with altitude, and when they are greater than one, the ratios increase with altitude, due to N growing with altitude. In both cases, the magnitude of the horizontal density gradient between the equator and the pole increases with altitude.

From Table 3, the density at 800 km at the winter pole is 41 per cent lower than the density at the equator at $t = 6$ h. The density at the north pole is 28 per cent higher than at the equator during August, September and October. Variations for other seasons and altitudes range between these values.

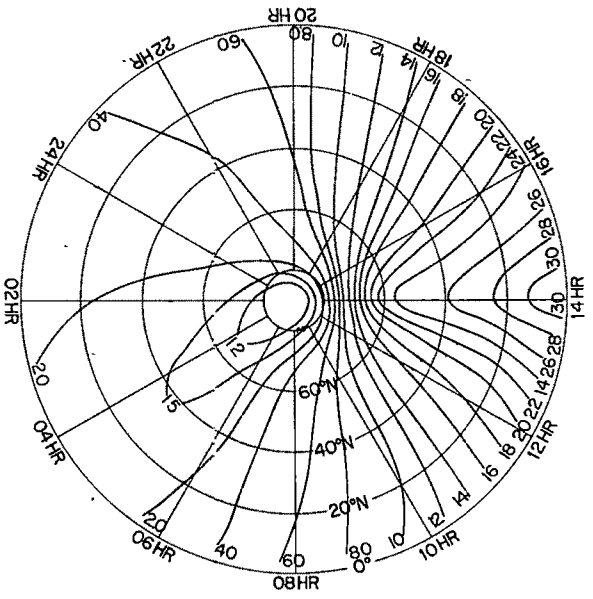

Fig. 6. 800-km relative density contours (north pole = 1·0) for northern hemisphere winter (Nov., Dec., Jan.)

Figs. 6, 7, 8, and 9 present contours (isopycnics) showing the relative density variation at 800 km (north pole = 1·0) in the northern hemisphere for winter, spring, summer and autumn, respectively. The latitude effect is taken into account by using the S' values in Table 2; the longitude (diurnal) effect is calculated from the tables given in ref. 5. In the figures, the longitudes are labelled in local time. These time labels apply up to about 70° N. The local time selected for the north polar region (above 70° N.) is 5 h for winter, 6 h for spring and autumn, and 7 h for summer, irrespective of longitude. In Fig. 6, winter, the latitude variation in density is much less than the longitude variation over most of the hemisphere, except for the region between 60° N. and the pole on the day side of the Earth. The maximum gradient occurs along the 14 h meridian. This same feature occurs on the maps for the other three seasons, although the gradient is not so great. The maximum density in the northern hemisphere in the winter occurs on the equator, where it is 30 times greater that at the north pole. In Fig. 7, spring, the minimum

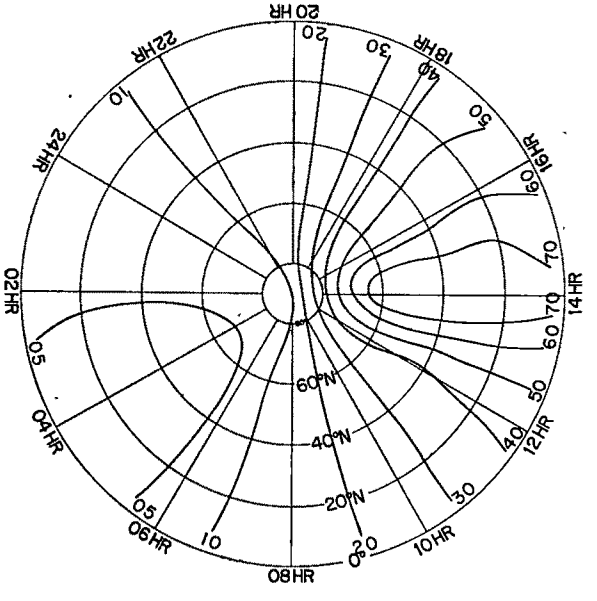

Fig. 8. 800-km relative density contours (north pole = 1 0) for northern hemisphere summer (May, June, July)

density has shifted south, from the pole to 60° N., while the maximum is on the equator at the average latitude of the sub-solar point. In Fig. 8, summer, the minimum has moved farther south to 30° N. latitude, while the maximum has moved north to about 20° N. In Fig. 9, autumn, the minimum is at about 60° N., but the maximum has not retreated to the equator with the Sun as expected; it has moved farther north to around 30°–40° N. This feature is a result of the anomalous heating indicated in the northern hemisphere autumn curve of Fig. 5.

It is obvious that the atmospheric density bulge caused by the Sun is not symmetric with latitude, except possibly during spring in the northern hemisphere. Contour charts drawn for other altitudes from 400 to 800 km will have their main features the same as those at 800 km. The contour configurations and locations of the maximum and minimum densities would not change with altitude, although the horizontal density gradients would decrease as the altitude diminishes. Below 400 km, the diurnal effect decreases in comparison with the latitude effect as the altitude diminishes, so that its influence on the contour pattern becomes much less. At 200 km, the contours (not shown; see ref. 13) are oriented more east–west than north–south, as at 800 km, so that the latitude density gradient is several times greater than the longitude density gradient over most regions. In winter and spring the lowest density is at or near the pole. The contours appear almost symmetric with respect to the pole, except for a slight bulge toward the pole along the 14-h meridian and a slight dip away from the pole along the 5-h meridian. In summer, the minimum density has shifted south to 50° N., while two maxima in density are indicated at 20° N. and 50° N. along the 14-h meridian. The gradients in summer are much weaker than spring and winter. In autumn the maximum density is at about 40° N., with a zone of relatively high density extending along this latitude on the day side of the Earth. At lower latitudes the contours are almost symmetric with the equator. King and Kohl[14] have used a density gradient from the 200 km contours[13] to deduce a mid-latitude meridional wind that is not greatly different from winds determined by means of sodium trail experiments.

The general configuration of the contours in Figs. 6–9, incorporating both the latitude and diurnal effects, will be quite similar for the southern hemisphere during the respective season and for the same altitude, except for autumn. For this, the northern hemisphere spring map can be taken to represent approximately the southern relative density pattern at the same altitude. The contour patterns at 400 km will be intermediate between those at 200 km and 800 km with respect to contour orientations and magnitudes of the gradients. It is not expected that the relative density variation with latitude at a given altitude and season, that is a consequence of relative variations of extreme ultra-violet radiation with latitude, would change greatly with changes in solar extreme ultra-violet radiation activity. The variations manifested in Table 2 and Fig. 5 should hold, at least as a first approximation, over the solar cycle, except possibly for the northern hemisphere autumn season. The contour configurations and gradients displayed in Figs. 6–9 should appear about the same at the maximum of the solar cycle. Calculations made with equation (2) indicate that the latitudinal gradients would intensify only slightly at sunspot maximum.

Therefore, a density variation with latitude and season can explain the semi-annual effect exhibited by S' in 1961 and 1962. The semi-annual effect is caused by the combined movement of satellite 1958 α and the Sun north

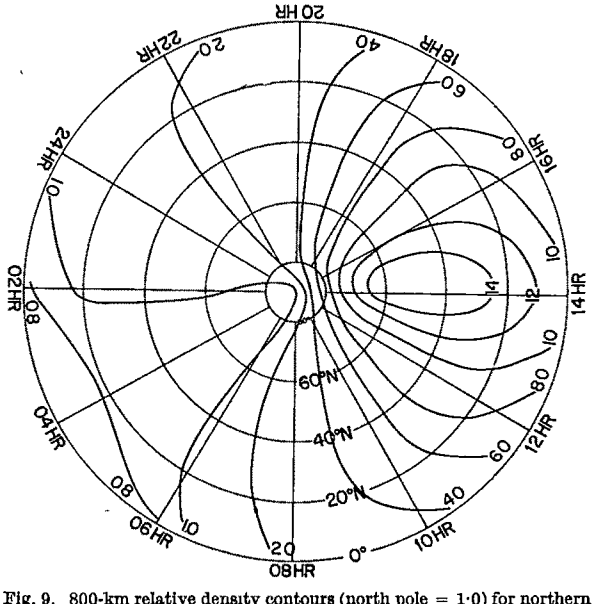

Fig. 9. 800-km relative density contours (north pole = 1·0) for northern hemisphere autumn (Aug., Sept., Oct).

and south of the equator. The marked minima in S' in either June or July from 1958 to 1962 result from a latitude variation in density and the perigee of 1958 α being at a maximum distance south of the sub-solar point in these months. A minimum should also be expected in S' in December or January. Such a minimum is indicated in 1961 and 1962; however, it is not apparent in 1958–1960. This minimum should not be so great as the June or July minimum because the Earth intercepts less extreme ultra-violet radiation during these latter months due to the greater Earth–Sun distance. The magnitude of the June or July minima cannot be completely explained on the basis of the seasonal curves in Fig. 4, but it is expected that curves for the individual months containing the solstices would indicate much greater latitudinal density gradients. The analysis of the data was unavoidably based on 3-month seasons because of the limited amount of S' data. The latitudinal density gradients for the individual months of a given season will differ from the 3-month curves, especially near the solstices. If a marked latitude density gradient does exist in the winter hemisphere near the solstices, as indicated by this analysis, then it should be reflected also in the P values for satellites other than 1958 α as their perigee latitudes change north and south of the equator. Other satellites do show the existence of a marked latitudinal density gradient, especially near the time of the solstices[15]. Thus, there seems to be little doubt that perigee latitude and the latitude of the sub-solar point are factors that must be taken into account in any analysis of the P variations, particularly near the solstices.

This work was supported by the Lockheed Independent Research Programme.

OBITUARIES

Dr. F. H. Pollard

Frederick Henry Pollard was born on June 6, 1907, in Swindon. After leaving school, he entered the University of Bristol in 1923, and took a bachelor's degree in 1927, reading chemistry as special subject. After taking a Diploma in Education in 1928, also at Bristol, he was appointed head of the Science Department at Thornbury Grammar School, Gloucestershire, from 1929 to 1937. In 1937 he moved to Hanley High School, where he proceeded to teach for a further 5 years. While at Thornbury Grammar School, Pollard was persuaded by Prof. W. E. Garner to work part-time for his Ph.D. The research work he carried out was on the infra-red spectra of carbon monoxide flames and he was awarded a Ph.D. in 1935. This interest, which he developed, he maintained until his untimely death.

In 1941, Pollard accepted the post of lecturer in inorganic chemistry at Bristol and was appointed senior lecturer in 1951, reader in 1954, and finally awarded the degree of D.Sc. in 1959. During the Second World War he worked with Dr. W. J. Dunning and others on the explosive *RDX*. Among the reactions he investigated were those between the oxides of nitrogen and low-molecular weight organic compounds; for example, formaldehyde and acetic acid. This interest, together with his responsibilities to the Department of Chemistry at Bristol, led him into the field of inorganic chemistry research. However, Pollard soon became convinced that more powerful methods of analysis would greatly increase the scope of inorganic chemistry. He began his research career relatively late in life, but, as is internationally recognized, he published an impressive collection of nearly one hundred scientific papers. The papers he published can be grouped under five headings: (*a*) inorganic chromatography; (*b*) gas chromatography studies; (*c*) thermal decomposition of organic nitrates; (*d*) carbides, silicides, nitrides and their reactions; and (*e*) co-ordination chemistry of new analytical reagents. Pollard began his work on inorganic chromatography in order to investigate how far paper and ion-exchange chromatography could be applied to the analysis of inorganic compounds with two ultimate aims: the development of a complete scheme of qualitative analysis; and the application of quantitative methods to the investigation of inorganic reaction mechanisms. At the time of his death, he was engaged on the establishment of a course in advanced analytical chemistry leading to the degree of M.Sc.

Pollard energetically shouldered the major burden of organizing the teaching of inorganic chemistry at Bristol, and was responsible for building up a vigorous school of teaching and research. It can be said that the foundation of inorganic chemistry at Bristol was his chosen life's work.

He took an active part in many University matters and had a knowledge and experience of schools and especially sixth-form work which was of great value in the matters of entrance requirements and student selection. Pollard was a member of the committee responsible for policy decisions on all building aspects of the new School of Chemistry, with the special duty of co-ordinating the scheme. He also found time to take an active part in the local and central activities of the Chemical Society, and the Society for Analytical Chemistry, serving on the councils of both bodies. In addition to this, he never severed his links with the teaching profession, in that he organized and lectured at conferences for teachers. In committee, Pollard's contributions, although often outspoken, were given with sincerity and deep feeling, in order that the correct choice might be made. He loved playing 'devil's advocate', a quality which often caused him trouble, being so easily misunderstood.

In spite of all these calls on his time, Pollard always took a very keen interest in the welfare of students, and anyone was welcome to ask his advice on problems of a personal nature. His quip to all of us was, "My door is always open". Characteristic of him was the effort, time and thought he gave to the development of student interchanges, especially between the Department of Chemistry, Bristol, and the Anorganische Institut, Technischen Hochschule, Brunswick, an association which developed from the lectures he gave in Germany in 1953 under the auspices of the Rockefeller Interchange Scheme.

His sudden death at the age of fifty-eight left his career sadly incomplete. During his life he never spared himself to serve his own generation, together with those generations in his charge which made up the University, to the best of his ability. Those of us who were his students are

deeply grateful. Although he listened with sympathy he could be a task-master—to all of us he was our 'father figure'. In the School of Chemistry at Bristol he will long be missed.

G. Nickless

Dr. Allen B. Du Mont

Dr. Allen B. Du Mont, the television pioneer of Cedar Grove, New Jersey, died on November 14, 1965, at the age of sixty-four. He was best known for his work in perfecting the cathode-ray tube.

Dr. Du Mont was born in Brooklyn, New York, on January 29, 1901, and he became a ship's wireless operator at an early age. He received his degree in electrical engineering from the Rensselaer Polytechnic Institute, Troy, New York, in 1924, and afterwards received honorary degrees from the Rensselaer Polytechnic Institute, the Brooklyn Polytechnic Institute, Fairleigh Dickinson University, New York University, and Montclair State College.

At the Westinghouse factory in Bloomfield, New Jersey, Dr. Du Mont worked on the development of high-speed manufacturing and test equipment for radio tubes. Later, as chief engineer of the De Forest Radio Company, of Passaic, New Jersey, he worked closely with Lee De Forest. In 1928 they established the first synchronized sight and sound television station *W2XCD*, using the Nipkow disk mechanical scanner at both the camera and receiver.

Recognizing the limitations of a mechanical television system, he then started his own company in 1931, later known as Allen B. Du Mont Laboratories, Inc. Dr. Du Mont afterwards expanded the company to produce a variety of cathode-ray tubes, the first commercially sold television receivers, television broadcast transmitters and studio equipment and an extensive range of scientific apparatus. He started the Du Mont Network with Station *WABD* before the Second World War and later linked it with the companion Station *WTTG* in Washington, D.C. From 1934 until the merger in 1960 with Fairchild Camera and Instrument Corporation, Dr. Du Mont served as director, president or chairman of the board of the Allen Du Mont Laboratories, Inc.

During the 'thirties, Dr. Du Mont worked on the development of radar systems and cathode-ray displays for both the Signal Corps and the Navy. His company contributed greatly in these fields during the Second World War and also to the Loran and Manhattan Projects, and later to nuclear propulsion instrumentation.

Dr. Du Mont served on the National Television System Committee, contributing to the formulation of broadcast standards for both monochrome and colour television. He was United States delegate to the International Radio Consultative Committee for consideration of international colour television standards. He collaborated extensively with the Federal Communications Commission in matters pertaining to the allocation of very high and ultra-high frequency television channels.

In 1943 he became the first president of the Television Broadcasters Association, which later combined with the National Association of Broadcasters for both radio and television.

Through the Allen B. Du Mont Foundation he took part in the establishment of Educational Television in co-operation with the Montclair State College in New Jersey and served on the New Jersey Commission for Educational Television. The Foundation also participated in and financed research in medical electronics.

Among his many awards, Dr. Du Mont received the Marconi Award of Achievement, the Horatio Alger Award, and he was made Chevalier de la Légion d'Honneur. In 1927 he was awarded the Westinghouse Award for Most Outstanding Accomplishment, in 1943 the American Television Society Award for Advancement of Commercial Television, and in 1944 the Television Broadcasters Association Award for the development of the cathode-ray tube.

Dr. Du Mont was one of the Public Governors of the American Stock Exchange and was vice-chairman of the Board of Trustees of Rensselaer Polytechnic Institute.

As an enthusiast for power boats, Dr. Du Mont won many awards for navigational accuracy in predicted log racing. With his boats, *Hurricane II* and *Hurricane III*, he did much to discover and interpret the multi-path and propagation effects of both television and radar signals.

Thomas T. Goldsmith, jun.

NEWS and VIEWS

Steacie Prize : Prof. N. Bartlett and Prof. J. C. Polanyi

Prof. Neil Bartlett, of the Department of Chemistry, University of British Columbia, and Prof. J. C. Polanyi, of the Department of Chemistry, University of Toronto, will share the 1965 Steacie Prize. The Prize consists of the income from the E. W. R. Steacie Memorial Fund to which colleagues and friends of the late president of the National Research Council contributed. It is awarded annually for outstanding work done in the natural sciences by younger people. Prof. Bartlett is cited for the first preparation of a chemical compound of a noble gas (*Proc. Chem. Soc.*, 218; 1962). The compound, $XePtF_6$, was prepared by the reaction of xenon with platinum hexafluoride. This startling experiment evolved logically from work on the fluorination of platinum and platinum compounds that Prof. Bartlett had been doing with D. H. Lohmann. The result immediately stimulated a flurry of experiments in other countries and soon a number of compounds of xenon and krypton had been prepared. The ramifications will not soon be exhausted. Prof. Polanyi was the first to observe infra-red chemiluminescence (Cashion, J. K., and Polanyi, J. C., *J. Chem. Phys.*, 29, 455; 1958), the occurrence of which he had predicted theoretically two years previously. The experimental techniques that he evolved have now been refined, and a wide range of atomic and molecular excitations caused by chemical reactions are being studied in Toronto and elsewhere. Five years ago, he published a proposal for a chemical laser (*J. Chem. Phys.*, 34, 347; 1961) and it has recently been shown to be practical. Both Prof. Bartlett and Prof. Polanyi are graduates of British universities. The former received a Ph.D. in 1958 from the University of Durham and the latter a Ph.D. in 1952 and a D.Sc. in 1964 from the University of Manchester.

Principal of the University of Stirling: Prof. T. L. Cottrell

Prof. T. L. Cottrell, professor of chemistry in the University of Edinburgh, will take up full-time duties as principal of the new University of Stirling in August. Prof. Cottrell graduated with honours in chemistry at the University of Edinburgh in 1943, and joined the Research Department of the Explosives Division of Imperial Chemical Industries, Ltd., at Ardeer. After working in the Physical Chemistry Laboratory at Oxford, he returned to Imperial Chemical Industries (Nobel Division) and became head of the Physical Chemistry Research Section in 1950. He was awarded the Meldola Medal of the Royal Institute of Chemistry in 1952. At the time of his appointment to the chair of chemistry in

Edinburgh in 1959, he was personal assistant to Sir Ewart Smith, deputy chairman of Imperial Chemical Industries, Ltd. Prof. Cottrell's main research interest in the University of Edinburgh lies in the field of energy transfer, with particular reference to the theory of chemical reaction rates. The research school which he has built up and directed continues to investigate transfer efficiency in molecule–molecule and electron–molecule collisions: the energy transfer from low-energy electrons to rotational or vibrational modes of molecules has received special attention. In addition to research papers in the scientific journals, Prof. Cottrell's published work includes *The Strength of Chemical Bonds* (Butterworths), *Molecular Energy Transfer in Gases* (with J. C. McCoubrey) (Butterworths), *Chemistry* (Oxford University Press) and his recently published *Dynamic Aspects of Molecular Energy States* (Oliver and Boyd). At the same time, he has been actively engaged in the teaching, planning and supervision of academic programmes, with special attention to undergraduate tutorial arrangements. One major change has been the establishment in Edinburgh of an honours B.Sc. degree in chemical physics, providing chemists with a more rigorous physical and mathematical approach to the subject. Formerly a member of the University of Essex Academic Planning Board, Prof. Cottrell is now a member of the corresponding Academic Advisory Committee, and thus brings to his new post a wide experience of teaching, research, planning and administration.

Materials Science at the U.S. National Bureau of Standards: Dr. H. E. Sorrows

The U.S. National Bureau of Standards has recently announced the appointment of Dr. Howard E. Sorrows as assistant to the Director of the Institute for Materials Research. Until his appointment, Dr. Sorrows was manager of the Space and Environmental Science Programs of Texas Instruments, Inc., a position that combined scientific management with profit responsibility. From 1959 until 1963, he initiated and managed a department for technical intelligence, long-range planning, and new product development. Dr. Sorrows has previously worked at the Office of Naval Research, the Navy Bureau of Ordnance, and at the White Oak Naval Ordnance Laboratory. He began his professional career at the National Bureau of Standards. Dr. Sorrows holds degrees from Baylor University and George Washington University and a Ph.D. from Catholic University. He has been active in a number of scientific societies, including the Institute of Electrical and Electronic Engineers, the American Institute of Aeronautics and Astronautics, Sigma Pi Sigma, Sigma Xi, the Dallas-Fort Worth Council of Scientific Societies and the Metropolitan Philosophical Society. He was chairman of the Dallas Section of the Institute of Electrical and Electronic Engineers during 1964.

United Kingdom Expenditure on Space Research

In a written answer in the House of Commons on January 25, the Secretary of State for Education and Science, Mr. A. Crosland, stated that the estimated expenditure by the Science Research Council on scientific space research in 1965–66 was £3·55 million. This included provision for the United Kingdom contribution to the European Space Research Organization of £1·75 million, most of which should be regarded as expenditure outside the United Kingdom. There was also a little expenditure outside the United Kingdom for purchase of equipment which had to be imported. In a further written answer on January 26, Mr. Crosland added that the Science Research Council organized the scientific space programme, which existed to make it possible for individual scientists, or groups of scientists, in universities or other institutions, to carry out researches in space. Hitherto, the main opportunities had been in the series of Anglo–American satellites. In future, the main opportunities would be in the European Space Research Organization and the National Aeronautics and Space Administration satellites. Also in a written answer, on January 25, the Minister of Technology, Mr. F. Cousins, stated that under its contract with the European Space Research Organization, the Atomic Energy Authority had completed its design study of the payload for the astronomical satellite project in which it makes proposals for satellite-borne instruments to enable ultra-violet and X-ray studies to be made of stars and nebulae. The Authority's design would be in competition with two other contract studies requested by the Organization, which was expected to take several months to assess them. In a further written answer, on January 27, the Minister of Aviation, Mr. F. Mulley, stated that the total estimated expenditure in 1965–66 by the United Kingdom on the space programme amounted to about £22 million, or 0·07 per cent of the gross national product, or a *per capita* expenditure of 5*s*. 3*d*. compared with 1*s*. in Belgium, 9*s*. 6*d*. in France, 6*s*. in the Federal Republic of Germany, and 2*s*. 3*d*. in The Netherlands. About 3,800 persons in the United Kingdom were employed on the British space programme and £15·32 million was provided in the 1965–66 programme for expenditure by the Ministry of Aviation on space research and development. This did not include expenditure to meet specific requirements of the Ministry of Defence and the Science Research Council, but does include a net payment of £2·21 million for the European Launcher Development Organization transactions.

Forestry Commission: Plans for Expansion

In reply to a question in the House of Lords on February 3, Lord Mitchison, Joint Parliamentary Secretary to the Minister of Land and Natural Resources, said that the Government had completed its review of planting to be carried out by the Forestry Commission. The programme for Great Britain provided for the Commission to plant 450,000 acres during the years 1964–73 and it had been decided that planting in England and Wales should continue within this programme. In Scotland it had been decided, in view of circumstances set out in the White Paper on the Scottish Economy, 1965 to 1970 (Cmnd. 2864), to increase the programme from the present level of 30,000 acres a year to 36,000 acres a year from 1969. In a written answer in the House of Commons on February 2, the Secretary of State for Scotland, Mr. W. Ross, stated that the Forestry Commission intended, as soon as circumstances permitted, to increase the number of professional, scientific and supporting staff in Edinburgh from seventeen to about forty. The location of the new building required was already being considered.

United Kingdom Atomic Energy Authority: Non-nuclear Research

In a written answer in the House of Commons on February 3, the Minister of Technology, Mr. F. Cousins, stated that scientific effort of the Atomic Energy Authority on work not directly connected with nuclear-energy was equivalent to that of about eighty professionally qualified or graduate scientists and engineers.

United States–Poland Exchange Programme

The U.S. National Academy of Sciences and the Polish Academy of Sciences have announced plans for a programme of exchange visits by scientists of the two countries. The agreement, which covers a 3-year period, became effective from January 1 and provides for exchanges in all the disciplines in which the two Academies are mutually competent: natural sciences, including mathematics; engineering sciences; and behavioural sciences. The new programme is flexible in its provisions

for both short-term visits by individual scientists to lecture, to conduct seminars, to survey research, or to exchange professional views and, for longer stays of up to 1 year, to carry out laboratory research or investigations in the field. Visits in each direction, totalling approximately 40 man-months per annum, are provided under the programme, with no necessary matching of either the number of exchanges or the scientific fields in which they occur. In addition to its provisions for the exchange of individual scientists, the agreement provides for co-operation between the two Academies in the field of scientific publications and documentation, including the exchange of information on research and documentation and programmes, and mutual assistance and advice on the exchange of books and scientific literature. This agreement is similar to the agreement which came into effect on January 1 between the U.S. National Academy of Sciences and the Council of Academies of Yugoslavia. Similar arrangements are also anticipated between the U.S. National Academy of Sciences and the academies of Romania, Hungary and Czechoslovakia.

Polish Academy of Sciences: Four-year Plan

The basic provisions of the 1966–70 Plan of the Polish Academy of Sciences Agencies are outlined by W. Nowacki in the Academy's *Review* for April–June, 1965 (10, No. 2; 38). The twenty-one institutes and forty-nine autonomous centres and agencies of the Academy now employ 5,600 persons, including 2,210 scientific workers, of whom 460 are independent; by 1970 it is anticipated that the present shortages in some disciplines will have been eliminated. In the social sciences, the research and development plan will continue the policy initiated a few years ago, but special attention will be given to the further development of the economic sciences. The establishment of an Institute for the Economic Sciences is proposed, as also is the development of research in pedagogies and psychology. In the biological sciences, the importance of biochemical and biophysical research is emphasized, and the development of microbiology and genetics is proposed. In medical and agricultural science and forestry, collaboration with the biological sciences will be strengthened, and research on the nervous system, on experimental and transplantation surgery, the physiology of ageing and of labour, and on human genetics, medical anthropology and human ecology is specially mentioned. In physics, special attention will be given to the development of the physics of solids, quantum electronics and the physics of low temperatures. In physical chemistry, the mechanism and laws of physico-chemical change, the methodology of separating multi-component mixtures, the physico-chemical foundations of metallic corrosion and the erosion of structural materials will be studied. In organic chemistry, the mechanism of reactions, the kinetics and catalysis of organic reactions, the utilization of indigenous raw materials and physiologically active substances are among the subjects proposed for research. Work on the physics of the rare and radioactive elements and the chemistry of plasma is also proposed. Research is also to be concentrated on the application of large automatic systems, new applications for analogue computers, the modelling of neuronal systems and on the methodology of planning.

The Cumberland Basin, Bristol

All large cities in Britain are to-day faced with an ever-growing traffic problem, and in this Bristol is no exception. In recent years, especially near the city centre and the city docks, traffic conditions at certain times became quite chaotic, particularly when the old swing bridge was opened at intervals during the day to permit the passage of shipping in and out of the docks. This swing bridge was the focal point for an enormous flow of traffic from the North, the Midlands, South Wales and South-West England; when ships were moving in and out of dock, road traffic built up into queues stretching for miles along either side of the Cumberland Basin. The problem has been considerably eased, however, by completion of what is known as the Cumberland Basin Bridges Scheme, a brilliantly conceived and executed design of bridges, viaducts and a new swing bridge, an account of which is contained in an illustrated article entitled "The Cumberland Basin Bridges and Viaducts", recently published (*Concrete Quarterly*. No. 66; July–September 1965. London: Cement and Concrete Association. 5*s*.).

The new lay-out is essentially an interchange of elevated roads on which north–south traffic crosses the river on the Avon Bridge, a three-span pre-stressed concrete structure. On the north bank of the river is constructed a spiral slip road and a branched ramp which take traffic to and from the old swing bridge. Just north of this interchange is the new swing bridge carrying the road across the entrance lock. Then, just north of this, the carriageways divide into four separate lanes; north-bound traffic can go straight on into Bristol City, or it can turn westward down a curving ramp towards Avonmouth via the Avon Gorge; two more curved ramps carry south-bound traffic up on to the new swing bridge. It is here that the swing bridge control tower is situated, whence changeable signs are operated to divert traffic streams down ramps towards the old swing bridge (east end of Cumberland Basin) when the new swing bridge is open for shipping. This most informative article gives technical details of the designs of the viaducts, the new Avon Bridge, and the new swing bridge. Apart from a panoramic photograph of the entire project, taken from the heights of Clifton, which clearly shows how traffic can flow in all directions without interruption, there are also photographs of a scale model of this scheme and its orientation, and of the Avon Bridge. A material factor in the overall design is that it has vastly improved the approaches to the city and has transformed much that was ugly into something much more pleasing which harmonizes the dockland with the well-known picture westwards, ". . . the towering cliffs of the Avon Gorge and Brunel's dramatic suspension bridge".

Improved Analysis of Earthquakes

According to a recent paper entitled "The Application of Phased Arrays to the Analysis of Seismic Body Waves", by J. W. Burtill and F. E. Whiteway (*Phil. Trans. Roy. Soc.*, No. 1091, 258, 421–493. London: H.M.S.O., 1965. 44*s*.; 6.60 dollars), the analysis of seismic body waves (that is, waves which have travelled through the earth rather than over its surface) has been facilitated by the use of phased arrays. This method has enabled more data concerning natural earthquakes and explosions to be obtained than has been so using the more conventional three-component set of seismographs. The array may first be used (often by signal delay and addition) to cut out random noise and microseisms, and then as a velocity and azimuth filter to eliminate unwanted waves, so that signal recognition is vastly improved. By these methods and by the use of correlation techniques, the velocities of various pulses across the array and their arrival time at one particular seismometer can be determined accurately. This information may then be used for the determination of the Earth's crustal structure by well-known methods. At ranges less than 25° seismograms are very complex. However, for ranges from 30° to 90° the effect of the propagation path has been shown to be small, and the results from explosions are in agreement with a simple symmetrical, impulsive source function. Nearly all natural earthquakes investigated, however, had asymmetrical source functions. At Yellowknife, waves having a length of at least 20 km have been observed and arrays of comparable dimensions are therefore necessary. Experiments have been, and are being, performed with line,

circular and cluster arrangements of seismometers and with various methods of weighting the signals (signal/noise power ratio, Tchebyscheff polynomials, etc.) in order to improve pulse recognition and measurement. Work on data analysers (chiefly for velocity and azimuth) is in progress. It might be added that seismological arrays are now in operation at Eskdalemuir, Scotland (United Kingdom Atomic Energy Authority), in Canada, in India, in Australia and in the United States.

Action of Ammonium Salts on Concrete

APART from ammonium sulphate, data on the action of ammonium salts on concrete are limited and, in some cases, conflicting. The problem has been investigated by Dr. F. M. Lea (Building Research Station), whose paper on "The Action of Ammonium Salts on Concrete" has recently been published (*Magazine of Concrete Research*, 22, 17; September 1965. Cement and Concrete Association, London, S.W.1). Dr. Lea studied the action of 5 per cent solutions of ammonium salts on a Portland, a Portland–pozzolana, and a high-alumina cement concrete. He found that ammonium chloride and nitrate solutions had a strong leaching potential, acting as dilute acids consequent on loss of ammonia by reaction with lime. Strengths of concrete cubes with all three cements fell by at least half in 4 years, without outward signs of deterioration. Examples are quoted of comparative compressive strengths (in lb./in.^{2}) of 4-in. cubes of 1 : 2 : 4 concrete; in the case of Portland cement, storage in water for 1 year gave the figure 6,310; in 5 per cent ammonium nitrate 1-year storage reduced this to 4,340; after 4 years the figure was 2,310; a 60 per cent Portland cement and 40 per cent spent oil-shale pozzolana mix gave corresponding figures of 4,960, 3,500 and 2,440; cubes of high-alumina cement showed a similar trend with corresponding figures 9,340, 7,180 and 4,400. Chemical analyses of some specimens tested show large reductions in the lime content of the cements.

In a further significant series of tests, to determine compressive strengths (in lb./in.^{2}) of 50 cm^2 cubes of 1 : 2 : 4 concrete, the following results were obtained: for Portland cement stored in water for 1 year, 7,320; the same stored for 3·5 years, 8,420. In 5 per cent ammonium nitrate, the corresponding figures were 4,525 and 3,050. In 5 per cent ammonium chloride, the figures for 1-year and 3·5-year storage were 4,140 and 2,110; and in 5 per cent ammonium sulphate, stored for 1 year, the figure was 825. High-alumina cement revealed similar reductions under the same conditions: in water the figures were 9,830 and 9,730 (storage for 1 and 3·5 years, respectively); with 5 per cent ammonium nitrate the reduction was from 4,685 to 1,520; with 5 per cent ammonium chloride the reduction was from 7,810 to 5,720; but with 5 per cent ammonium sulphate, only 10,110 to 9,115. (All the foregoing results are means of tests on four cubes.) Regarding the reaction of ammonium sulphate on Portland cement, the formation of calcium sulpho-aluminate producing expansion is dominant, and Dr. Lea attributes this to its solubility being lower than that of the nitro- or chloro-aluminates.

Control of Tuberculosis

International Work in Tuberculosis, 1949–1964, is the title of a reprint from the *WHO Chronicle* which reviews the tuberculosis programme of the World Health Organization (Pp. 32. Geneva: World Health Organization; London: H.M.S.O. 1965. 2 Sw. francs; 3*s*. 6*d*.; 0.60 dollars). In 1948, the World Health Assembly decided to make tuberculosis control one of the priority programmes of the World Health Organization. Initially, there were two main aspects of the work of the World Health Organization: the demonstration of modern methods of tuberculosis control to developing countries and collaboration with the United Nations Children's Fund in mass BCG vaccination programmes. In 1959, the work took a new direction. Research into the epidemiology of tuberculosis assisted by the World Health Organization had shown that some of the conventional ideas about the disease were erroneous, and clinical research assisted by the World Health Organization had shown that domiciliary treatment of tuberculosis by drugs was as effective as, and cheaper than, institutional treatment. The experience of the World Health Organization with classical methods of control had shown that training and demonstration projects would not, by themselves, promote new programmes and that mass BCG programmes also had limitations. A new approach to the control of tuberculosis was therefore evolved, namely, the concept of the national tuberculosis programme adapted to the needs and resources of each country and planned by a national tuberculosis institute. The first of these institutes was opened in Bangalore in 1959, and the success of the programme developed there exceeded expectations. This concept is now being used to deal with the widely differing problems met with in countries now receiving help from the World Health Organization for tuberculosis control. Research has been, since 1949, an integral part of the tuberculosis control programme of the World Health Organization, and thirty-four national institutions in twenty-four countries are now taking part in this work. The activities range from the establishment of a standard tuberculin test to the development of cheap and effective standard chemotherapy. This publication contains seven sections on various aspects of control programmes and five sections on research and diagnostic procedures, epidemiology, immunization, chemotherapy and chemo-prophylaxis, and systems analysis.

Effect of Experimental Haemorrhage on Haemoglobin Plasma Iron and Total Iron-binding Capacity in Dairy Calves

WHEN K. C. BREMNER, of the Division of Animal Health, and J. A. Ronald, of the Wheat Research Unit, C.S.I.R.O., withdrew blood samples of 10, 20 and 30 ml./kg body-weight from healthy dairy calves, the plasma total iron-binding capacity increased (*Austral. J. Exp. Biol. and Med. Sci.*, 43, Part 5; October 1965). Plasma iron concentrations also increased significantly after bleeding at the two higher levels, but were unaffected by a blood loss of 10 ml./kg. Calves bled daily for 2 weeks at rates of 2, 4 or 6 ml./kg/day also had significantly increased plasma total iron-binding capacity. Blood losses of 2 or 4 ml./kg/day resulted in an elevation of plasma iron concentration. However, phlebotomies of 6 ml./kg/day eventually caused a marked depression of plasma iron levels, but when the bleedings stopped, plasma iron concentrations increased to abnormally high values. It is suggested that the increased plasma iron levels were due to an increased absorption of dietary iron. Labile iron reserves in the experimental calves were estimated to lie within the range 1·0–1·4 g, and were associated with liver concentrations of non-haem iron of about 30 μg/g wet liver. In calves, levels of non-haem iron in liver tissue of less than 20 μg/g appear to be indicative of iron deficiency.

Exchange Scheme between Britain and India for Younger Scientists

DURING the past 2 years there has been in operation an exchange scheme designed to establish or maintain contact between British universities or research institutes and their counterparts in India through visits by younger scientists. The scheme, originally proposed by the (then) scientific adviser to the Indian High Commission in London, provides for six visits of between 6 weeks and 4 months duration by younger British scientists to India,

arrangements for attachments to suitable institutions being made by the Indian University Grants Commission. A similar number of visits by Indian scientists to Britain are also provided for, attachments being arranged through the British Council. Nine British scientists have visited India under the scheme since its inauguration and it is hoped to arrange a further six visits during the period April 1, 1966–March 31, 1967. Applications from British scientists, preferably between the ages of 27 and 35, are now invited. Further information and forms of application can be obtained from the Director, Science Department, the British Council, 59 New Oxford Street, London, W.C.1. The closing date for applications is March 15, 1966.

The Paul Instrument Fund Awards

THE Paul Instrument Fund Committee has made grants as follows: £3,250 to Prof. A. F. Gibson, professor of physics in the University of Essex, for the development of devices to extend the application of infra-red lasers; £700 to Dr. E. T. Hall, director of the Research Laboratory for Archaeology and History of Art, Oxford, for the construction of a geophysical magnetic simulator; £5,000 to Mr. A. R. Luxmoore, of the Engineering Department, University College, Swansea, for the construction of a 'Moiré-scope'—a special optical instrument sensitive only to the deformations of a body, and not affected by any rigid body movements (closely comparable with the conventional polariscopes used in photo-elastic measurements of stress). The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Institute of Physics and the Physical Society and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much-improved types of physical instruments and apparatus for investigations in pure or applied physical science".

Council for National Academic Awards : Degree Courses

Statement No. 3 from the Council for National Academic Awards deals with the approval of courses in science, technology, arts and social studies, leading to the award of the honours or ordinary degrees of B.Sc. or B.A. (Council for National Academic Awards. *Statement No. 3.* November 1965. Pp. 15 London: Council for National Academic Awards, 1965). For this purpose the Council has established two Boards of Studies: the Committee for Science and Technology, and the Committee for Arts and Social Studies. The *Statement* deals with the admission of students to courses, the duration and content of courses including training in sandwich courses, with teaching and with examination arrangements. Students who successfully complete honours courses will be granted degrees in four classes: first-class honours; second-class honours (first and second divisions); and third-class honours.

University of Newcastle upon Tyne : Vice-Chancellor's Report

THE Vice-Chancellor's report to the Court and Council of the University of Newcastle upon Tyne for the period August 1, 1964–July 31, 1965, is accompanied by departmental reports and lists of publications, arranged under departments (Pp. 152. Newcastle upon Tyne: The University, 1965. n.p.). It records 3,996 undergraduate and 587 postgraduate students; 1,554 students entered in October 1965, compared with 8,702 applications, making a total of 628 postgraduate and 4,247 undergraduate students. Deep concern is expressed over the erosion of the value of recurrent grants in the present quinquennium. A grant from the Department of Scientific and Industrial Research enabled the University to establish the first centre in Britain for retrieving information on medical science. A university grant enabled members of the University to participate in the 1965 Fezzan Expedition, while the Exploration Society sent an expedition to Afghanistan and undergraduate expeditions to Iceland and to Greece.

Announcements

DR. J. E. RICHEY, formerly district geologist, H.M. Geological Survey, Scotland, has been awarded the Neill Prize for the period 1963–65 by the Council of the Royal Society of Edinburgh, in recognition of his investigations on the structure of the tertiary volcanoes of Scotland and Northern Ireland.

MR. W. T. COOPER has been appointed national chairman of the Institute of Fuel, Australian Membership, in succession to Prof. N. Y. Kirov.

THE Deutsche Akademie der Naturforscher, Leopoldina has announced the appointment of the following new members: Prof. E. Hasche (Bad Berka); Prof. E. Lesky (Vienna); Prof. H. von Mayersbach (Nijmegen); Prof. H. Merxmuller (Munich); Prof. K. W. Merz (Freiburg).

A COURSE on "Information on a Shoe-string" will be held by ASLIB on March 17. Further information can be obtained from the Education Officer, ASLIB, 3 Belgrave Square, London, S.W.1.

A CONFERENCE on "Stresses in Service", under the auspices of the Joint British Committee for Stress Analysis, will be held at the Institution of Civil Engineers during March 23–25. Further information can be obtained from the Secretary of the Conference, Institution of Civil Engineers, Great George Street, London, S.W.1.

A ONE-DAY meeting of the Biological Group of ASLIB to discuss the problem of training for university students, research workers and librarians in the biological field will be held at the Northampton College of Advanced Technology on March 25. Further information can be obtained from Miss P. I. Edwards, Department of Botany, British Museum (Natural History), Cromwell Road, London, S.W.7.

A SYMPOSIUM on "Potatoes for the Food Processing Industries", sponsored jointly by the Fruit and Vegetable Preservation Research Association and the Department of Food Science and Technology of the Borough Polytechnic, will be held at the Borough Polytechnic on March 17. Further information can be obtained from Dr. D. B. Smith, Department of Food Science and Technology, Borough Polytechnic, London, S.E.1.

A COURSE of six evening lectures on "The Mechanical and Metallurgical Aspects of Metal Forming" will be held at the Bradford Institute of Technology on Wednesdays during February 23–March 30. The programme will include: introductory metallurgical principles; crystal structures and imperfections; application of dislocation theory; introduction to the theory of plasticity; mechanics of metal deformation. Further information can be obtained from the Registrar, Bradford Institute of Technology, Bradford 7.

A CONFERENCE on "Electronic Processes in Low Mobility Solids", sponsored jointly by the Departments of Physics and Glass Technology of the University of Sheffield, will be held in the University during April 18–20. The purpose of the meeting is to discuss transport phenomena, optical, dielectric and other properties associated with electron (or polaron) hopping and tunnelling in solids in which normal band theory may not be applicable. Further information can be obtained from Dr. A. E. Owen, Department of Glass Technology, The University, Northumberland Road, Sheffield 10.

FIELD AND GLASSHOUSE EXPERIMENTS

A SYMPOSIUM on the "Layout, Management and Recording of Experiments in Field and Glasshouse" was held in London on November 24, 1965, by the Horticultural Education Association, in association with the Association of Applied Biologists and the British Ecological Society. In opening the symposium, Prof. L. Broadbent, president of the Horticultural Education Association, said that members had requested an opportunity to learn something about the principles underlying experimental work without becoming too involved in statistics.

The first paper was by Dr. S. C. Pearce (East Malling Research Station), who discussed "Determining the Objects of the Experiment" so that data could be analysed and results interpreted. Before starting an experiment its objective should be clearly defined and a different hypothesis, suggested by examination of the data, should not be tested although the arithmetic involved might be virtually the same. Variability within even apparently uniform material existed and, indeed, was the basis of the 'analysis of variance'. In good designs, which were based on randomization and replication, variability from external causes, such as soil and environment, could be calculated and removed from the total variation and the likelihood of incorrect results in an experiment could be determined. Although the 'coefficient of variability' was often useful in comparing one experiment with another in a series of experiments, it could be most misleading when used in isolation, as its numerical value depended to some extent on the inherent variability of the material used in the experiment.

D. Cooke (University of Sussex), in considering "The Design of the Experiment", said that a critical examination ought to be made after data had been analysed. This should reveal whether the design selected had been 'efficient', that is, whether the experiment had been worth doing at all and what inferences could be made. He suggested that perhaps it was a pity that there were no critics in science comparable to art critics. He explained why the appropriate unit to use with many experiments involving glasshouse crops is a whole glasshouse and not part of one. It should be recorded in this connexion that nine similar glasshouses have been built at the Glasshouse Crops Research Institute in order that multi-factorial experimental designs may be used.

He also suggested that the effect of 'scaling up' in horticulture should be investigated. Experience had shown that marked effects in experiments were often very much reduced when applied on a large scale, but in the horticultural industry, unlike chemical engineering, no scale models were available.

In discussing the 'three R's' of experimentation—restriction, randomization and replication—Cooke recommended that the major sources of variation often warranted a careful examination. If the residual variation per plot, after allowing for variation due to treatment and block, was large, a different design for future experiments should then be considered to see whether a greater amount of variation could be accounted for and so removed in the analysis of variance.

D. Price Jones (Imperial Chemical Industries, Ltd.), opening the discussion on the foregoing two contributions, commented that pilot trials, general surveys and small simple experiments which could be repeated over a wide range of soils still played an important part. Judging by the many and varied questions which followed, there is a real desire for guidance from statisticians on such technical matters as the number of plots to use, how to score when qualitative effects are being assessed, how precise measurements should be, and on many other day-to-day matters which have to be decided by experimentalists, even if a statistician is available for overall planning.

"Multivariate Analysis", the subject of J. N. R. Jeffers (Forest Research Station), was introduced by the chairman, Prof. A. H. Bunting (University of Reading), as a logical basis for understanding biological situations. Now that data are processed by electronic computers, lengthy arithmetical calculations may quickly be done, but the real advantage, as Jeffers said, is not in the speed of working but in being able to use techniques hitherto not even contemplated because of their complexity. In the past, when a number of different variates have been measured in an experiment (for example, dry weights, lengths, number of leaves), analyses have been carried out for individual variates, or two of them have first been combined in some way (for example, as a proportion or percentage). In multivariate analysis, however, even when variates are measured in different units (grams, centimetres, etc.), provided they are independent (that is, there is not a constant relation between two of them), a mathematical relationship which includes all the variates may be found to describe a biological situation and comparisons may then be made between different situations. Such a mathematical equation does not immediately show the relative importance which may be attributed to the different variates, but Jeffers outlined how this problem could be solved by a calculation known as principal component analysis. In this analysis data are transformed at the outset to counteract the effect of different units being used and to ensure that one factor is not overweighted because of the arbitrary selection of the original dimensions (for example, measuring in millimetres rather than in centimetres). Two of the transformations in use involve finding a variance-covariance matrix between every set of variates and the computation of a correlation matrix. Jeffers concluded by referring to canonical analysis, another technique which may be used when comparisons are made of biological material and data for a number of variates exist. He forecast that fewer experiments would probably be done in the future, but that they would be larger and better planned and would require the advice of a statistician at all stages, particularly in the interpretation of the results.

It was stimulating to hear of the possibilities of obtaining so much information from one experiment, provided a statistician was at hand to clarify the complex situation which would arise. The ecologist, on the other hand, starts with a complex interacting system containing plant and animal species, different soils and so on, and attempts to describe it mathematically. Dr. M. B. Dale (University of Hull) discussed numerical techniques in ecological research and showed how investigations fall into two main groups, those in which the frequency with which a particular factor is present is recorded and those in which only their presence or absence is noted. In both cases, much depends on the initial decision as to which items to investigate. Samples are taken from appropriate sites, either at random or in some systematic way, rather like taking records at stated intervals of time. The data may be analysed by an 'ordination' technique when the samples are put in sequence, so that the two which differ most are

at the ends. A number of such sequences are possible according to the factors chosen as being most important. A more usual method of handling the data is by 'classification' when like samples are grouped together. In both cases a personal decision as to the relative importance of the different factors involved determines the results; it should be remembered that what seems unimportant at the time of sampling in ecological work may be of great interest in later years. Although both principal component analysis and canonical correlation analysis are being tried, some other analysis, more easily interpreted, is required. Dale is hopeful that, by introducing some form of 'weighting', he will be able to produce a satisfactory classification method.

In the final general discussion, Jeffers said that suitable statistical techniques were becoming so advanced that the service of one professional statistician would be required to about six research workers, if full value was to be obtained from an experiment. With the present shortage of statisticians that ideal seems remote, but members of the symposium welcomed Prof. Bunting's announcement that, beginning in October 1966, there would probably be a one-year M.Sc. course in biometry at the University of Reading. Nevertheless, research workers will still have to formulate a hypothesis, be able to discuss the layout of the experiment with a statistician, supervise the day-to-day management and obtain appropriate data. Finally, even if the analysis is obtained for him by the statistician, with the use of an electronic computer, he must be able to discuss the interpretation of the results and translate them into biological terms. A working knowledge of the 'language' of statistics and of the underlying principles would seem to be increasingly necessary for all those responsible for field and glasshouse experiments and for those interested in the application of their results. It is hoped that another symposium will be arranged to continue the education of the non-statistician who uses statistical tools.

Members of the three organizations responsible for the symposium are greatly indebted to Mr. J. H. Walker, of East Malling Research Station, for arranging this symposium and to the various speakers for presenting their specialized subjects to an audience of horticulturists and biologists, many of whom had had no formal training in statistical methods.

M. E. Marston

EUROPEAN JOURNAL OF CANCER

THERE is, and has been since 1936 when the International Union Against Cancer was founded, extensive international collaboration and exchange in the field of cancer research. This co-operation has been stimulated in recent years by the idea of an international institution of cancer research located in Europe and also by the efforts of the World Health Organization. At the European regional level such groups as the European Committee for Cancer Chemotherapy and the European Committee for Human Tumour Investigation are also playing their part in encouraging inter-European collaboration between clinicians and scientists engaged in the study of cancerous diseases. It is logical that these European groups and their associated workers should now have a journal which will provide a forum for the exchange of ideas and information. This journal is the *European Journal of Cancer* which made its first appearance in June of last year*.

The editorial advisory board of the new journal consists of workers of repute in the cancer field drawn from nine European countries, and the policy of the board will be to publish original work in the field of experimental and clinical cancer research, papers giving the results of planned clinical studies and also general reviews on subjects of particular relevance to these researches and studies.

The first issue contains eight papers from laboratories and centres in Belgium, France, Holland and Italy, so justifying the adjective European in the journal's title. There are two papers from the Radiological Institute of the Netherlands. One by L. M. van Putten presents the results of studies on the effects of different storage techniques on mouse and monkey cell suspensions, and the other is by H. S. Reinhold, in which he describes a combined mechanical and enzymatic method for obtaining a single cell suspension from solid tumour tissue. The method allows a concentrated suspension of a large number of cells to be prepared in a short time. The paper from Milan by G. G. Guidotti and others is on the inhibiting effects of aliphatic aldehydes on protein synthesis in Yoshida ascites hepatoma cells. The paper from France consists of a review by G. Mathé on immunological reactions in their relationship to the development of cancer and the possibility of immunotherapy in its treatment. The four remaining papers come from Belgium. R. van Nie and P. J. Thung contribute a paper on the hormonal influence of pregnancy on mouse mammary tumours and its implication for tumour behaviour and progression. J. Hildebrand and C. Coers report six cases of polyneuritis with severe damage to peripheral nerves in patients receiving intravenous injections of 3–5 mg vincristine per week for varying periods. Vincristine is an alkaloid extracted from the periwinkle flower which, although very toxic, has shown promise as an effective agent in Hodgkin's disease and certain leukaemias, and to a much lesser extent in other tumours. This study confirms previous reports of polyneuropathy caused by vincristine treatment. Another paper dealing with a chemotherapeutic agent is that by Y. Kenis and others, again from Brussels, which reports the results of treating patients suffering from Hodgkin's disease, various lymphomata and leukaemias, with a methylhydrazine derivative. The fourth paper, from a centre in Belgium, consists of a general review of the literature reporting cases of metastatic liver cancer associated with renal dysplasia. This paper is contributed by G. Buyse and others from the hospital at St. Gilles and Brussels University.

The November issue contains the papers given at the International Symposium on the biological characterization of human tumours which was held in May of last year. That these papers should have appeared in print so soon after their formal presentation shows a promptness in symposium publication which is as rare as it is commendable.

The standard of typography and lay-out, the quality of the paper, and the illustrations are of the high standard which we have come to expect from the Pergamon Press. A particularly pleasing aspect is the way in which the bibliographical references are given in full with the titles of the papers quoted. This greatly increases the value of the list of references and is a house rule which could well be copied by other journal publishers. The annual subscription price to individuals is a very reasonable £5 5*s*. The annual subscription price to libraries is £14, which follows this publisher's usual practice of being at a higher differential rate: a practice which I deplore.

(15 dollars) per annum for individuals who write directly to the publisher and certify that the journal is for their personal use. (Oxford Pergamon Press, Ltd., 1965.)

THE BAAS BECKING BIOGEOLOGICAL RESEARCH LABORATORY, CANBERRA, AUSTRALIA

THE Baas Becking Biogeological Research Laboratory, which will shortly move into its permanent home at the new Bureau of Mineral Resources Building in Canberra, was established in July 1965, under the joint sponsorship of the Commonwealth Scientific and Industrial Research Organization (C.S.I.R.O.), the Bureau of Mineral Resources (B.M.R.) and the Australian Mining Industry Research Association (A.M.I.R.A.). The broad objective of the research work is to investigate the biological and chemical processes associated with the formation of mineral deposits and with other geological phenomena.

The Laboratory is named after the late Dr. L. G. M. Baas Becking, who was one of the first to recognize the possibility that biological, in particular microbial, activity may play an important part in the genesis of sulphide ores.

Laurens G. M. Baas Becking was a research scholar of wide interests, equally renowned in the United States, Java, Australasia and his native Netherlands. His investigations of microbial involvement in the syngenetic deposition of minerals arose from an interest in the milieu of life and its environmental limits. This interest first brought him to Australia in 1936 to investigate, in collaboration with Dr. J. Reuter, life in salt lakes, as part of his research into the effect of organisms on changes in soil, lakes, estuaries and on mineralization.

For a long period, the mode of deposition of certain types of large base-metal ore deposits was open to conjecture; two theories were advanced, sedimentary deposition and hydrothermal emplacement. By the early part of the twentieth century, the hydrothermal theory was widely accepted. Most ore deposits, and virtually all sulphide ore deposits, were believed to have been formed by a process of hydrothermal introduction of the ore minerals at high temperature, into fractures and by metasomatic replacement, and it was assumed that the textures of the ore minerals were the result of this emplacement. It followed that these textures could therefore be used to determine the depositional history of the deposits.

In the 'fifties the view gained ground that this was not the only way in which base metal ore deposits were formed. Some of the ore deposits emplaced in sedimentary and metamorphic rocks were in fact laid down with these rocks. This process was termed syngenesis. The mechanisms of syngenetic deposition are still mostly unknown, but the possibility has been recognized that biological factors might be involved.

In Australia, during the late 'fifties and early 'sixties, some investigations into the general problem of syngenetic sulphide ore formation were initiated. Laboratory research was pursued into the low-temperature formation of sulphide minerals, crystallization of amorphous base metal sulphides at high temperature under defined conditions and the biological formation of mineral sulphides. The biological studies were undertaken by Dr. Baas Becking, who succeeded in demonstrating the formation of a number of metal–sulphide minerals by sulphate-reducing bacteria in artificial sea water at room temperature.

In 1960, a number of mining companies, operating through the Australian Mineral Industries Research Association, joined with the B.M.R. and the C.S.I.R.O. in financing a small research unit to enable Dr. Baas Becking to pursue his studies. Ill health unfortunately prevented Dr. Baas Becking from doing this, but his work was generally confirmed and appreciably extended by Dr. K. L. Temple during the period 1961–63. In general, the work reached the stage where it could be visualized that under certain conditions the biogenic formation of sulphides might be an important factor in the formation of some economic ore deposits. As a result of this work, it was decided to embark on a more ambitious research programme and the three supporting organizations formed the Baas Becking Biogeological Research Laboratory.

Initial emphasis will be placed on investigations to establish the relationship of biological factors to the natural physico-chemical environment with particular reference to the possible role of these factors in the formation and transformation of sulphide minerals. Investigations will include the response of micro-organisms to heavy metals; biochemistry and physiology of oxidative and reductive sulphur transformations; role of organisms in the concentration of mineral elements; physico-chemistry of low-temperature mineral synthesis; mobility of sulphides under the influence of temperature and pressure and the interaction of mineral types; and biological leaching of low-grade sulphide minerals.

It is planned to extend research at a later stage to include other important minerals of possible biogenic origin such as carbonates and phosphates. Dr. P. A. Trudinger and Mr. W. M. B. Roberts will be in charge of research operations, responsible to a committee of management under the chairmanship of Mr. Haddon F. King.

LOCAL HEALTH SERVICES

EXPENDITURE on health by local authorities has been rising faster than expenditure on the National Health Service as a whole. The National Health Service accounted for more than 10 per cent of the total expenditure in 1964, compared with little more than 7 per cent in 1949. Expenditure on health services by local authorities more than trebled between those years, to reach a total of £107 million for the United Kingdom in 1963–64. This information is given in an Office of Health Economics report * which emphasizes the changing pattern of work now being carried out by local health authorities.

The largest proportional increases in expenditure are due to the provision of more 'home helps' (from £2·3 million to £12·3 million) and to extending the services for the mentally ill in the community (from £1·2 million to £9·3 million). The number of 'home helps' employed rose from about 19,000 in 1949 to more than 60,000 in 1964. Four-fifths of all their work is looking after elderly people at home; the report points out that, for every elderly person visited by a 'home help', there are two others who need help with their housework and are not getting it. Practically no community care was provided for the mentally ill before the start of the National Health Service. By 1964, 156,000 people outside hospital were benefiting from local mental health services.

* Office of Health Economics. *The Local Health Services*. Pp. 40. (London: Office of Health Economics, 1965.) 2*s*. 6*d*.

The largest actual increase in expenditure has been in the ambulance services. This has risen from £6·5 million in 1949 to £18·8 million in 1964. The total number of patients carried has risen even more, from 7 million in 1949 to almost 20 million in 1964. Four-fifths of ambulance work consists of carrying patients to and from out-patient departments, and a much larger proportion of such patients are now travelling by ambulance. At the start of the Health Service only one out of every ten journeys between the home of an out-patient and the hospital was made by ambulance; now, one in every four journeys is by ambulance.

The report emphasizes how difficult it seems to be to persuade people to accept immunization against infectious diseases. Only 66 per cent of infants born in 1961 were immunized against poliomyelitis. It comments that "the dangers of infectious diseases have diminished to an extent undreamed of 30 years ago; but there can be one disadvantage of a successful vaccination campaign. This is the comfortable but false assumption by the general public that it has been a once-for-all battle which has eliminated the threat forever".

The report directs attention to the large differences between local health expenditures in different parts of Britain. They range from the expenditure by Northampton County Council of £1 3*s*. per head of population to that of £3 1*s*. 2*d*. by the Cardigan County Council. In terms of personnel, this means a two-fold variation in numbers of health visitors, and a three-fold variation in numbers of 'home helps', nurses and midwives. The report comments that "in this case, geographical factors are undoubtedly important; but, in general, it is not easy to say whether variations between the level of provision in different areas are due to differences in need, differences in financial resources, or differences in the appreciation of the value of the services". These differences in levels of expenditure between different parts of Britain are expected to continue during the next ten years.

The report calls for "a substantial operational research programme" to "evaluate in depth the services actually provided by typical high spending and low spending areas". The results, it says, could be coupled to those of community studies; these have already suggested that there are many needs unmet, especially in the case of the elderly at home.

Commenting on plans for the future, the report points out that "the trend towards community care and the consequent necessity for close co-operation between the various sections of the tripartite Health Service have provided an opportunity for the local health authorities to play a more prominent part". However, the plans for the next ten years prepared by the local health authorities "imply a slackening rate of expansion in their local health services which becomes very marked after the end of this decade".

The report suggests that the falling off in expansion of the services planned by the authorities must be taken primarily as a reflexion of the difficulty of forecasting for a situation in which there are still so many unknowns. The changing responsibilities of the general practitioner, the increasing skill in early diagnosis and the development of day hospitals are but a few of the external factors which must affect the function of the local health authority. What is important is to maintain flexibility, and, above all, to avoid recrimination if the present rate of expansion of the local health services in fact continues far into the 1970s. Those who framed the National Health Service made a "miscalculation of sublime proportions" in assuming that its costs would not rise as the Service developed, and much criticism of actual expenditure resulted. The ten-year plans of the local health authorities inevitably appear to contain a similar fallacy, and it would be unfortunate if these were eventually to result in similar misunderstanding.

"In this connection", says the report, "it is encouraging to note that the new National Plan takes a more expansive view of the local health services in the future. While the local authorities forecast an increase in current expenditure of only 4 per cent in 1968–69, with an annual average of 1·5 per cent in the following five years, the National Plan refers to the annual rate of increase having risen to 6·5 per cent in 1969–70. Whereas local authorities forecast an increase in net revenue expenditure of 30 per cent in the decade from 1964–65, the National Plan forecasts an increase of 34 per cent within the first five years."

THERMODYNAMICS OF NEW GENERALIZED TRANSPORT LAWS FOR LIQUIDS, GASES AND ELECTRONS IN MATTER

By Prof. M. A. MELEHY
University of Connecticut, Storrs, Connecticut

It is well known that thermodynamics constitutes the foundation of numerous conventional principles and theories in the physical, life and engineering sciences. Some important parts of thermodynamics are the criteria of thermal equilibrium. It has been almost invariably assumed that for any thermodynamic system in thermal equilibrium, the chemical potential is constant everywhere in the system for each constituent. Such a criterion, as will be shown in this article, can only be justified if the particle concentration in the system is uniform everywhere for each constituent. The last statement is substantiated by at least one case treated in the classical work of J. W. Gibbs, to be referred to later in this article.

For the particular case of electrons in solids, it is well known that these particles obey the Fermi–Dirac[1,2] statistics, and that at constant temperature the Fermi-level is equal to the chemical potential. Thus, it has been conventionally concluded that in thermal equilibrium the Fermi-level for electrons must also be constant throughout any solid. This assumption alone constitutes a foundation for much of the transport theory of electrons in solids as it is known to-day.

It has been pointed out that the validity of assuming that the Fermi-level is constant in thermal equilibrium would not be justifiable for electrons in non-degenerate *p-n* junctions[3]. Similar objections have been raised for electrons in any heterogeneous solid[4]. If the arguments in refs. 3 and 4 are valid, one would expect that the conventional criteria of thermal equilibrium as a whole might involve some basic misconceptions. If so, it should then be possible to show these misconceptions by new direct arguments and conventional thermodynamics. Attempting to point out and treat this serious matter will be the main objective of this article.

To investigate the criteria of thermal equilibrium, new phenomenological laws will be formulated. These will describe the transport of conduction electrons in any form of matter, and more generally the transport of particles in fluids enclosed in stationary containers, under

the action of any finite number of processes of different nature, in and near static equilibrium. The new transport laws lead to the fact that in thermal equilibrium generally the differentials of the chemical potential, the Helmholtz free energy, and the Gibbs function must all become exact differentials rather than necessarily vanish, as conventionally assumed.

The new phenomenological criteria of thermal equilibrium will be verified quantum statistically for boltzon, fermion and boson particles. It will be shown that these criteria, unlike the conventional ones, make it possible to formulate what is to be called the equation of internal state for liquids. The latter equation is based on the virial theorem. It will be further demonstrated that Fick's law for ideal classical isothermal liquids is a consequence of the new transport laws and the equation of internal state for liquids.

The transport laws to be formulated are meant to describe steady-state conditions associated with time-independent processes. Under such conditions conceivably the concentration of particles is not time-dependent. Thus, there is no accumulation of particles anywhere and for charged particles there are no displacement[5] currents at any point. These assumptions clearly hold in static equilibrium and for many other interesting situations in dynamic equilibrium.

(1) Transport Correspondence Principle

Since the discovery of the Seebeck effect[6] in 1826, the Peltier effect[7] in 1834, and other transport phenomena in solids, the electron transport theory in its conventional form has developed along lines almost completely different from those of what is at present known as network or circuit theory. The non-network transport theory seems to be essentially based on thermodynamics and some supposedly accepted criteria of thermal equilibrium.

Circuit theory, on the other hand, has been largely based on seemingly different laws. These include Ohm's law and Kirchhoff's voltage and current laws. It is rather difficult to explain why the foundations of circuit theory and the rest of the transport theory have been formulated differently. Perhaps the conditions of circuit theory appeared to be considerably more special than those of the transport theory in general. Thus it so happened that the fundamental laws, which simultaneously link nearly all electron transport phenomena in matter, including those of circuit theory, and more generally systems of mobile particles, seem to have passed unnoticed. This article attempts to describe this missing link and some of its fundamental new implications. We begin in this section with postulating what is to be called 'the transport correspondence principle'. This principle may be stated as follows: to every time-independent law in network theory there corresponds another to hold in general for the electron transport in any form of matter, in and near static equilibrium, provided that the network law and its conditions are entirely describable in terms of non-restrictive physical quantities. As will be explained in section (4), a similar statement may be made for any system of mobile particles, if the system is enclosed in a stationary container.

The term 'non-restrictive' used here is meant to describe physical quantities, which are not characteristic of only one process of a specific nature. Rather they must signify a universal physical quantity. Thus, we may describe the electron force, energy, and volume concentration as non-restrictive physical quantities. On the other hand, the electric or magnetic-field intensities, according to the definition here, are restrictive physical quantities. Each one is characteristic, and indicative of the existence of a specific physical situation of a specific nature.

The following sections will describe a number of interesting general consequences of this new fundamental principle.

(2) The Electron Force–Current Generalized Law in Passive Media

This section is concerned with formulating the first electron generalized transport law. To explain this law, consider Fig. 1, which represents a loss-less battery with an e.m.f. V_B connected to a resistor R. The current I_R through R may be described in terms of the voltage V_R across R by Ohm's law as follows:

$$I_R = V_R/R \tag{1}$$

Notice here that all the three quantities in equation (1) belong to one element; namely, the resistor R.

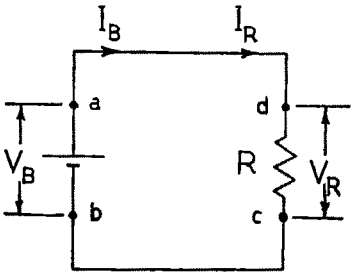

Fig. 1. A loss-less battery connected to a resistive element R

Let us next write an expression for the battery current I_B. This will be:

$$I_B = V_B/R \tag{2}$$

Notice here that while I_B and V_B both belong to the battery, R does not belong to that circuit element. Rather it belongs to an element outside the battery. Thus we may state the following: The current through any resistor is determined by Ohm's law in terms of all the variables of that resistor. However, the current through an e.m.f. source cannot be determined by all the variables of the source. Rather complete information for the whole closed loop is needed to determine the current in the e.m.f. source.

Let us next transform equation (1) and the statement just made into a non-restrictive form so that the transport correspondence principle of section (1) may be applied. To do so, consider a point P within the resistor. Let the electric field intensity at P be $\mathbf{E}$. The electron current density $\mathbf{J}_n$ at P may be expressed as:

$$\mathbf{J}_n = \mu' n(q\mathbf{E}) \tag{3}$$

Here μ' and n are respectively the electron mobility and volume concentration at point P, and q is the magnitude of the electron charge. It should be noticed here that equation (3) can be derived from equation (2) and the definition of mobility.

It is apparent that $(-q\mathbf{E})$ in equation (3) represents the electrostatic force $\mathbf{f}_e$ acting on the electron at P. Let us now imagine that $\mathbf{f}_e$ at P has been replaced somehow by another equal force $\mathbf{f}$ of any nature. It is conceivable that the electron current density $\mathbf{J}_n$ would remain unchanged, provided that $(\mu' n)$ remained constant. Therefore we may write:

$$\mathbf{J}_n = -\mu' n\mathbf{f} \tag{4}$$

and say that $\mathbf{f}$ is the generalized force per electron at P. The nature of this force here, of course, is totally unimportant.

It must be remembered here that equation (4) is a non-restrictive transformation of Ohm's law described by equations (1) and (3). Equation (1) is only valid for a resistor but not an e.m.f. source. Similarly, equation (3) is only valid in solid regions not containing e.m.f. sources. Such regions will be referred to as 'passive regions'.

In order to apply the transport correspondence principle to this last-mentioned condition, again we must state it in a non-restrictive way. Regions involving only e.m.f. sources, hereinafter called 'active regions', have merely spatially varying electron energy not caused by electric

currents. This will mean that the electron energy in such regions has gradients everywhere at zero currents. These energy gradients will be defined as 'motive' or 'active' forces.

Examples of active regions in solids may be the transition region in a p-n junction or generally the heterogeneous regions in solids, isothermal or otherwise. The term heterogeneous here is used in the same sense as is defined in ref. 4. In all such regions, as is well known, the electron energy varies spatially everywhere even in thermal equilibrium, that is, when there is no electron current anywhere.

Examples of passive regions in solids include all homogeneous isothermal regions such as uniformly doped p- or n-regions in p-n junctions. In such regions the electron energy is constant so long as the electron current is zero everywhere, that is to say, in thermal equilibrium.

On the basis of the preceding discussion, one may state the first generalized transport law for electrons in any form of matter as follows. Near and in static equilibrium, the steady-state electron current density $\mathbf{J}_n$ at a point P is related to the time-independent force per electron $\mathbf{f}$ at that point by: $\mathbf{J}_n = -\mu' n \mathbf{f}$, provided that P lies only in a passive medium. Specifically this relation is meaningless if P is in an active medium. A similar statement of this law may be made for any system of mobile particles, provided that the system is enclosed in a stationary container.

(3) Loop Conservation of Energy for Conduction Electrons in Matter

The object in this section is to discuss what is to be called the 'second generalized transport law' for electrons in any form of matter. Using the same line of reasoning as that of the previous section, one may formulate this law, which can be stated as follows. Under steady-state conditions, the line integral of the active force per electron around any closed loop in any form of matter must be equal to the line integral of the passive force per electron around the same loop. This is so whether or not there are currents at various points of the medium. When the actual electron flow along the loop is taken to be a reference for direction, active and passive, forces along the reference direction must be assigned the same sign. For example, both forces must be considered positive. As will be explained in the next section, a similar statement may be made for any system of mobile particles, provided that the system is enclosed in a stationary container.

It should be indicated here that the aspect of conservation of energy of this law is, of course, quite familiar. What is new, however, is the statement of the law in terms of the force per particle in active and passive media.

(4) Generalized Criteria for Static Equilibrium of Electrons in Matter and of Mobile Particles Generally

The object in this section is to arrive at the necessary and sufficient condition for the static equilibrium of any one constituent of a system of particles, compressible or otherwise, if the system is enclosed in a stationary container and is subject to any finite number of time-independent processes of different nature. Before discussing this general problem, a derivation will be presented for a system of a specific form, namely, electrons in various forms of matter.

For electrons in solids, the conditions to be sought have been stated in ref. 4 on the basis of a seemingly paradoxical argument. It is now possible on the basis of the first and second generalized transport laws to derive it on more rigorous grounds. To do so, consider any medium containing active and passive regions. Let the conduction electrons in the medium be in static equilibrium everywhere. Thus, according to the first generalized transport law, the force per electron is zero, at every point lying in a passive region. Imposing this relation on the second generalized transport law, expressed in the previous section, we obtain:

$$\oint \mathbf{f}.\mathrm{d}\mathbf{s} = 0 \qquad (5)$$

Here $\mathbf{f}$ represents the generalized force per electron in the active regions of the considered medium and the integration is carried around every closed loop in the system. In view of Stokes's theorem[8], equation (5) may be expressed in the microscopic form as:

$$\nabla \times \mathbf{f} = 0 \qquad (6)$$

The generalized conditions for the static equilibrium of electrons in various forms of matter expressed by equations (5) and (6) may be further described in a third form. From the point of view of energy, the quantity $\mathbf{f}.\mathrm{d}\mathbf{s}$ merely represents the infinitesimal work done, $\mathrm{d}W$, per electron when it is transported a distance $\mathrm{d}s$. If the integral of $\mathrm{d}W$ must vanish around every closed loop, it follows that everywhere:

$$\mathrm{d}W = \text{an exact differential} \qquad (7)$$

Such a property would constitute a third generalized criterion for the static equilibrium of electrons in any form of matter.

So far the main concern has been to treat the transport of electrons in matter near and in static equilibrium. Such sub-atomic particles indeed constitute one form of a system of mobile particles. A question of considerable interest may be raised as to whether it would be possible to apply all the generalized transport laws formulated for electrons for all other mobile particles near and in static equilibrium. If a positive answer exists, one must be able to show that conduction electrons in matter are at least as general hydrodynamically and otherwise as any other type of particles such as fluids.

Let us first investigate the question of compressibility for electrons in matter. That electron conduction can involve electron compressibility even without a recombination process may be directly shown by considering, for example, the conduction in any medium free of such a process. Under steady-state conditions, it is well known that the continuity equation[9] for electrons leads to:

$$\nabla \mathbf{J}_n = 0 \qquad (8)$$

It is also well known that the density of the electron current is related to the carrier flow velocity $\mathbf{v}$ at any point by:

$$\mathbf{J}_n = -qn\mathbf{v} \qquad (9)$$

From equations (8) and (9), it follows that:

$$\nabla.(n\mathbf{v}) = 0 \qquad (10)$$

The implication of the preceding equation is that $\nabla.\mathbf{v}$ will vanish only if n is constant. Hence, whenever conduction by electrons occurs in any medium and $\nabla n \neq 0$, then $\nabla.\mathbf{v} \neq 0$. Examples, for which $\nabla n \neq 0$, are the interfaces between any two different metals or between a solid and a liquid. It is well known hydrodynamically[10] that a fluid is considered to be 'incompressible' if $\nabla.\mathbf{v} = 0$, and conversely. Thus, conduction by electrons in any medium where $\nabla n \neq 0$ indeed involves compressibility even in the absence of the process of recombination. This particular statement will have some especially important consequences to be discussed in section (6) concerning the question of validity of the conventional thermodynamic criteria of thermal equilibrium.

From the preceding discussion, it seems reasonable to assume that the two generalized transport laws and condition for static equilibrium do apply generally to systems of mobile particles which are enclosed in stationary containers. In further support of this statement, it should be indicated that, when the first generalized law of transport is applied to particles moving in a one-phase fluid, it reduces essentially to Stokes's law[11]. For such particles, of course, the fluid represents a passive region.

The applicability of the new generalized condition for static equilibrium to various kinds of systems of particles

subject to various types of processes may be further illustrated by some interesting examples. Consider a closed bottle containing water. Let this bottle be shaken before it is placed on a stationary table in an isothermal neighbourhood. After a sufficiently long time in the absence of any gravitational fields other than that of the Earth, there will be no flow in the water at any point. Static equilibrium will be established in this case despite the fact that every particle of the liquid of mass m is acted on by a gravitational force $\mathbf{f}_g = m\mathbf{g}$. Here $\mathbf{g}$ is the gravitational acceleration. Notice here that $\nabla \times \mathbf{f}_g = 0$, and equation (6) is satisfied.

Let us next consider a conducting solid near an antenna but electrically isolated from it. Clearly if the antenna is radiating electromagnetic waves, currents will be induced in the solid. Let now the antenna be fed from a d.c. source, so that only an electrostatic field will exist around the antenna where the solid is. Conceivably conduction electrons in this case will be in static equilibrium everywhere in the solid. According to Maxwell's equations[12], however, when the electric field $\mathbf{E}$ is not time-varying, then curl $\mathbf{E} = 0$ everywhere around the antenna including at all points of the solid. Thus curl $\mathbf{f}_e = 0$. Here $\mathbf{f}_e$ is the electrostatic force per electron at any point on or within the solid. Thus equation (6) is again satisfied.

Another interesting example lies within the domain of circuit theory. It is well known that the most general condition for a vanishing current everywhere in a multi-mesh network is that the e.m.f. around every closed loop is zero. This condition is equivalent to saying that the work done per electron around any closed loop is zero. Static equilibrium of electrons in this case will be established, regardless of whether the passive circuit elements were linear or non-linear. Notice here that equation (5) is satisfied.

From equations (5), (6) and (7), and the preceding examples, it is apparent that the generalized conditions necessary and sufficient for static equilibrium may be stated as follows. If a system of mobile particles, enclosed in a stationary container, is involved in any finite number of time-independent processes of any nature, it will be in static equilibrium everywhere within the container, if for each constituent due to each and every process: (1) the work done per particle around any and every closed loop is zero; (2) everywhere within the container the infinitesimal work done per particle dW when transported a distance ds is an exact differential; or (3) there exists an acting force $\mathbf{f}$ per particle the derivatives of which exist and which is irrotational everywhere within the container.

Thus far, the generalized conditions of static equilibrium for systems of mobile particles have been discussed for a number of processes which are not thermodynamic in nature. In the remaining sections, it will be demonstrated that these general criteria of static equilibrium indeed will equally apply to purely thermodynamic processes.

(5) Fundamental Thermodynamic Equations, the Chemical Potential, and the Thermodynamic Transport Energy Function

This section will be primarily concerned with summarizing the four fundamental thermodynamic equations associated with a thermodynamic system. From one of these equations, a rigorous new definition will be arrived at for the important quantity known as the chemical potential. The concept of thermodynamic fields will also be introduced.

Consider a one-constituent thermodynamic system. Let part of that fluid consist of N particles and occupy a volume V. Let U be the internal energy of the N particles, T its absolute temperature, P its pressure, and S its entropy. Let V be sufficiently small so that the pressure and temperature of the fluid are uniform throughout V. In an infinitesimal quasi-static[13] change involving a reversible process for which N is constant[14]:

$$dU = T\,dS - P\,dV \qquad (11)$$

Here $(T\,dS)$ represents the increment of heat energy given to N and $(P\,dV)$ is the amount of work done by the particles while expanding.

The preceding equation is a consequence of the first and second law of thermodynamics. Suppose, however, that during the occurrence of the process a small number dN of new particles entered quasi-statically the volume V. The first law of thermodynamics then will require that:

$$dU = T\,dS - P\,dV + \mu\,dN \qquad (12)$$

Here the quantity $(\mu\,dN)$ represents the amount of work done on the original particles by the dN particles, which entered the volume V. It has been assumed here that each of the dN particles has the same μ. This particular point will be further discussed shortly. The quantity μ is generally known as the 'chemical potential'. This fundamental quantity was probably first introduced in the classical work of J. W. Gibbs[15].

It is important to arrive at a rigorous definition for μ, which can be used consistently to describe generally the transport phenomena under isothermal conditions and even otherwise. Any basic definition for μ must clearly be expected to stem from the preceding fundamental thermodynamic equation. Since according to that equation $(\mu\,dN)$ represents the work done on the N particles by the dN particles introduced into the volume V, it must be that μ is the average work done by each particle introduced into V, due to a purely thermodynamic process.

The definition just stated for μ lacks completeness and, in fact, general validity. The reason for this is that the definition assumes simply that μ can always exist mathematically throughout the entire thermodynamic system, inside and outside the volume V. Unfortunately, this is not the case. As will be discussed in section (7), the quantity $d\mu$ will not necessarily be an exact differential except under isothermal conditions. Thus, under non-isothermal conditions, the integral of $d\mu$ between any two points must in general depend on the path linking these points. If we still wish to define μ uniquely under non-isothermal conditions, we must then specify a path and an arbitrary value for μ at some arbitrary point on the chosen path.

An analogous situation to this arises in electromagnetic wave theory. For example, in a medium in which an electromagnetic wave is propagated, it is not possible to specify the electric potential V at every point of the medium. This is so since, according to Maxwell's equations[12], the electric field intensity is rotational at every point. Thus, the quantity dV is not an exact differential and the integral of dV between any two points must depend on the path. If, however, a path is specified, such as a certain thin open loop of wire, and a reference point chosen on the path for measuring V, then it is possible to define uniquely the electric potential at every point of the wire.

To summarize the preceding discussion, we may define the chemical potential μ at any point within a sufficiently small volume V enclosing N particles to be the average work done, under the action of a purely thermodynamic process, on the N particles by each particle introduced into V after having been transported quasi-statically from a reference point along a prescribed path. It is meant by a sufficiently small volume here that the pressure and temperature are uniform throughout the volume V.

In problems connected with the transport of mobile particles it would be convenient to think in terms of the average work done on, rather than by, a transported particle. Thus, it would be desirable to introduce a new quantity ν which may be defined generally at any point A within a sufficiently small volume V enclosing N particles to be the average work done, due to a purely thermodynamic process, on each particle transported from an arbitrary

reference point along a prescribed path to point A. Let this function be called the thermodynamic transport energy function, or the transport function.

Comparison of the definition of μ and of ν clearly indicates that:

$$\nu = -\mu + C \tag{13}$$

Here C is an arbitrary constant, which will be zero if the reference points for both ν and μ coincide.

For the particles described earlier, one may write the important thermodynamic relation[16]:

$$U = ST - PV + \mu N \tag{14}$$

It is now possible to derive a fundamental expression for the differential of the chemical potential $d\mu$. This can be done by equating dU, as described by equation (12), to that determined from equation (14), and solving for $d\mu$. Carrying out these steps, we obtain:

$$d\mu = -(S/N)\,dT + (V/N)\,dP \tag{15}$$

The quantities (S/N) and (N/V) may be defined as the entropy per particle, s, and the particle concentration, n, respectively. Thus, equation (15) may be rewritten as:

$$d\mu = -s\,dT + (1/n)\,dP \tag{16}$$

or as:

$$\nabla\mu = -s\,\nabla T + (1/n)\,\nabla P \tag{17}$$

From equations (13) and (17), it follows that:

$$\nabla\nu = s\,\nabla T - (1/n)\,\nabla P \tag{18}$$

Since the dimension of ν is that of energy, clearly the dimension of $\nabla\nu$ is that of a force. Thus we may define $\nabla\nu$ as the thermodynamic generalized (acting) force per particle, and denote this quantity by $\mathbf{f}_t$. The term generalized refers to the fact that the two components of $\mathbf{f}_t$, although thermodynamic in nature, are of fundamentally different characteristics.

The reader will recognize the last term in equation (18) to be what has been called in refs. (3) and (4) the 'diffusion force per particle' and designated by f_d. From the original derivation of $\mathbf{f}_d$, in ref. (3), it is apparent that it is a mechanical force, caused by a pressure gradient. The middle term in equation (18), however, would exist only when there is a temperature gradient. Since its dimension is that of a force, it may be defined as the thermal effective force per particle, and will be designated by $\mathbf{f}_T$.

In view of the preceding definitions, and equation (18), the thermodynamic generalized force per particle may be expressed as:

$$\mathbf{f}_t = \mathbf{f}_T + \mathbf{f}_d \tag{19}$$

where:

$$\mathbf{f}_T = s\nabla T,\ \mathbf{f}_d = -(1/n)\,\nabla P \tag{20}$$

Equations (16) and (17) are well-known relations[17], even though they are not commonly used. It so happens, however, that these equations have some particularly interesting implications concerning the new criteria of thermal equilibrium to be formulated in section (7).

In addition to equation (12) there are three other fundamental thermodynamic equations. In the differential forms, these are:

$$d\mathcal{F} = -S\,dT - P\,dV + \mu\,dN \tag{21}$$

$$dG = -S\,dT + V\,dP + \mu\,dN \tag{22}$$

$$dH = T\,dS + V\,dP + \mu\,dN \tag{23}$$

Here $\mathcal{F}$ is the Helmholtz free-energy function, G is the Gibbs function, and H is the heat function or enthalpy.

(6) Critique of Conventional Criteria of Thermal Equilibrium

It is well known that in thermal equilibrium, for any thermodynamic system, the temperature must be constant everywhere. In addition to this condition, there are others commonly assumed. The object in this section is to show that, except for the condition of constant temperature, for some thermodynamic systems, the other conventional criteria of thermal equilibrium do not necessarily hold.

(*A*) *The pressure and chemical potential.* It is generally assumed that under thermal equilibrium conditions, the chemical potential for almost any thermodynamic system is constant everywhere. This assumption is considered to hold, for example, for electrons in any solid, regardless of the spatial distribution of the electron concentration. The criterion of thermal equilibrium just described follows at once from equation (16) only if the pressure is constant throughout the thermodynamic system.

Let us first discuss whether the conventional assumption concerning pressure is really true for all systems. One may be able to cite, of course, some examples for which $dP = 0$ in thermal equilibrium. On the other hand, one can find also many other interesting systems for which this assumption does not hold. Examples of these are: (1) an isothermal atmosphere around an isolated planet, the gravitational field of which is sufficiently strong to hold the gas; (2) the electrons in two different isothermal solid crystals in physical contact.

In the first example, the pressure can be shown[18] to decrease exponentially as a function of height in thermal equilibrium. In the second example, since the vapour pressure P for electrons may be defined[19,20] quantum-mechanically on the basis of the virial theorem, P will indeed be a function of the concentration n. The latter is not the same in the two different solids under consideration in thermal equilibrium. Therefore, across the interface between the two solids $dn \neq 0$ and $dP \neq 0$ in thermal equilibrium.

The conclusion that $d\mu \neq 0$ whenever $dP \neq 0$ in the two preceding examples is an inevitable consequence of equation (16). It might be of historical interest to state that the example of an atmosphere in thermal equilibrium happens to have been treated by Gibbs[21], who also has concluded that for that case $d\mu \neq 0$ in thermal equilibrium. Clearly it may now be stated that under thermal equilibrium conditions, $d\mu$ will never vanish in any system wherever $dP \neq 0$; that is, wherever $dn \neq 0$.

The conventional argument supposedly leading to a constant μ in thermal equilibrium is not usually based on the aspect of pressure as just explained. Rather it is based on an equation similar to (21), which may be written as follows:

$$d\mathcal{F} = -S\,dT - P\,dV + \sum_k \mu_k\,dN_k \tag{24}$$

The last term is a summation of more than one product, since it is needed here supposedly to test whether or not the particles would have the same chemical potential at different points.

The conventional argument supposedly proving that for electrons in solids $d\mu = 0$ in thermal equilibrium proceeds as follows. First it is assumed that $d\mathcal{F}$ is zero. This particular assumption will be shown in the next section to be unjustifiable. For the time being, however, let us accept the conventional assumption that $d\mathcal{F} = 0$ in thermal equilibrium. It is then reasoned conventionally that if dN particles were transferred from point A to B at constant volume, then:

$$d\mathcal{F} = (\mu_a - \mu_b)\,dN = 0 \tag{25}$$

From equation (25) it would follow that $\mu_a = \mu_b$.

The weakness in the preceding argument is that if dN particles were transferred from point A of high particle concentration n_a to point B of low particle concentration n_b, this could not possibly be done at constant volume. To explain this point let us calculate specifically the volumes occupied by dN particles at point A and at point B. At the former point, the volume $dV_a = (dN)/n_a$, and at point B, the volume $dV_b = (dN)/n_b$. Thus $dV_b = (n_a/n_b)\,dV_a$. If points A and B are on either side of, for example, an interface between a metal and a p-type semiconductor, respectively, the ratio of (n_a/n_b) could be 10^{16} or higher. Thus, the assumption that dN particles could be transported at constant volume in any system is obviously invalid. Clearly the volume will remain unchanged only if $n_a = n_b$, that is, in any region where $\nabla n = 0$. This particular conclusion was arrived

at in section (4) in connexion with the hydrodynamic interpretation of equation (10).

(*B*) *The function G.* It is generally stated that across the boundary line between a liquid and its vapour, in thermal equilibrium $dG = 0$. The conventional reasoning supposedly leading to this result uses equation (22), which is here rewritten for convenience, $dG = -S\,dT + V\,dP + \sum_k \mu_k\,dN$.

To show supposedly that $dG = 0$ in thermal equilibrium across the boundary line between two phases, it is conventionally stated that if dN particles were transferred from phase i to j, then this would be done at constant pressure. Thus $dG = (\mu_i - \mu_j)\,dN$. Since it is conventionally believed that $\mu_i = \mu_j$, it is then concluded that $dG = 0$.

There are two objections in the preceding argument. The first concerns the validity of assuming that $\mu_i = \mu_j$. This matter has been already discussed in the preceding subsection. The second objection is less obvious. It is concerning the assumption that across the boundary, $dP = 0$, which can be shown to contradict the virial theorem. This particular point will be further discussed in section (8).

(7) New Criteria of Thermal Equilibrium

In the previous section, a number of arguments were presented challenging the validity of the conventional criteria of thermal equilibrium. The object in this section is to formulate new criteria of thermal equilibrium. It will be shown that under such conditions, wherever the concentration is non-uniform, each one of the quantities $d\mu$, $d\mathcal{F}$, dG and dH must become an exact non-vanishing differential, and the thermodynamic generalized force per particle must become irrotational.

(*A*) *The chemical potential, and the thermodynamic generalized field.* In section (5) it was demonstrated that under the action of a purely thermodynamic process, the work done per particle transported a distance ds is merely dv and that is equal to $(-d\mu)$. According to equation (7), the condition necessary and sufficient for the static equilibrium of any system of mobile particles enclosed in a stationary container is that the work done dW per particle transported a distance ds must be an exact differential. Therefore, it may be concluded at once that at constant T:

$$d\mu = -dv = \text{exact differential} \qquad (26)$$

Thus from equations (17), (18), (19) and (20) it follows that, in thermal equilibrium, $\mathbf{f}_t = \mathbf{f}_d$ and each must become irrotational.

Equation (26) is clearly a consequence of the new transport laws, which are phenomenological. Before discussing any of its consequences, equation (26) must be verified quantum-statistically.

Let us first consider an ideal classical gas, which has concentration gradients in thermal equilibrium. An example of this will be electrons in a non-degenerate p-n junction or gas in an isothermal atmosphere of a planet. The equation of state for either of the two cases is well known[22] to be:

$$P = nkT \qquad (27)$$

The quantity $d\mu$, at constant T, may be found from equations (16) and (27) to be:

$$d\mu = (kT/n)\,dn = d(kT \ln n) \qquad (28)$$

Equation (28) is clearly an exact non-vanishing differential wherever $dn \neq 0$. If $dT \neq 0$, then $d\mu$ would not be an exact differential necessarily.

The non-vanishing exactness of $d\mu$ in thermal equilibrium should be possible to verify quantum-statistically in any general situation wherever $dn \neq 0$. Consider, for example, conduction electrons in any solid crystal, degenerate or otherwise, in which the electrons have a concentration gradient in thermal equilibrium. Examples of this situation are p-n junctions, heterojunctions, or any solid–solid interfaces. Let the volume energy density of quantum states[23] $g(\varepsilon)$ be parabolic. It is well known that electrons in solids generally obey the Fermi–Dirac statistics. For such particles, it has been shown in ref. 4 that in thermal equilibrium $\mathbf{f}_d$ must become irrotational. In view of equations (16) and (20), it can be shown that $d\mu$ must become an exact non-vanishing differential wherever $dn \neq 0$. It can be further shown that $\mathbf{f}_d$ may be rotational and $d\mu$ inexact if $dT \neq 0$.

(*B*) *Helmholtz free energy* $\mathcal{F}$. It will be demonstrated here that in thermal equilibrium, and only then, $d\mathcal{F}$ becomes an exact non-vanishing differential wherever $dn \neq 0$. To do so, consider equation (21), which in general will be:

$$\begin{aligned} d\mathcal{F} &= -P\,dV + \mu\,dN - S\,dT \\ &= -d(PV) + V\,dP + d(\mu N) - N\,d\mu - S\,dT \end{aligned} \qquad (29)$$

From equations (15) and (29), at constant T, it follows that:

$$d\mathcal{F} = -d(PV) + d(\mu N) \qquad (30)$$

Thus, $d\mathcal{F}$ is an exact non-vanishing differential at constant T, since $d\mu$ is so.

(*C*) *Gibbs function G.* It is also possible to show that in thermal equilibrium, dG becomes an exact non-vanishing differential wherever $dn \neq 0$. To do so, consider equation (22), which is:

$$dG = V\,dP + \mu\,dN - S\,dT \qquad (31)$$

or:

$$dG = V\,dP + d(\mu N) - N\,d\mu - S\,dT \qquad (32)$$

From equations (15) and (32), it follows that:

$$dG = d(\mu N) \qquad (33)$$

This completes the proof.

(*D*) *The heat function, or enthalpy H.* It is again possible to demonstrate that in thermal equilibrium, dH becomes an exact non-vanishing differential wherever $dn \neq 0$. To do so, consider equation (23), which is:

$$dH = T\,dS + V\,dP + \mu\,dN \qquad (34)$$

In view of equations (31) and (34), we may write:

$$dH = d(ST) + dG \qquad (35)$$

Since, in thermal equilibrium, dG is an exact non-vanishing differential wherever $dn \neq 0$, so also is dH.

(*E*) *Reconstruction of the principle of detailed balancing.* It has been pointed out in refs. 3 and 4 that the common interpretation of the conventional principle of the detailed balancing implies a fundamental conflict with the existence of the Peltier effect. The cause of the conflict may here be explained to be simply a violation of the first generalized transport law. According to that law, the rate of steady-state flow cannot be expressed at any point in an active region only in terms of the physical constants there. Thus, for example, one cannot say that in the transition region of a p-n junction, in thermal equilibrium, the diffusion and drift current densities are equal and opposite at every point. What one can say for this particular case and for any region containing mobile particles, without violating the new transport laws, may be described by the new statement of the principle of detailed balancing, as follows. At any point in any system in static equilibrium, for every particle, of a specific constituent, which is crossing a given area per unit time in one direction, under the action of each process of a specific nature, there is another particle of the same constituent crossing in the opposite direction.

Thus, according to this new law, under static equilibrium conditions, each process must become conservative and hence independently gives rise to a vanishing flow for each constituent at each point, within the stationary container enclosing the fluid. This is in sharp contrast with the conventional statement of the principle, which assumes that the balance in thermal equilibrium is not caused by the individual processes; rather it is caused by all the processes combined.

(8) The Equation of Internal State for Liquids, and the Coexistence of Liquid–Vapour Phases

The conventional concept of pressure in liquids is probably one of the oldest in physics. The concept, for example, presents itself in connexion with the law of buoyancy discovered by the Greek scientist Archimedes (287–212 B.C.). In the eighteenth century, this concept has been used by Daniel Bernoulli (1700–1782) to formulate some well-known laws of hydrodynamics.

The conventional concept of pressure for liquids, henceforth called 'external pressure', is in sharp contrast with what is to be named the 'internal pressure'. The latter will be defined for liquids according to the virial theorem. Internal pressure, as the name implies, describes a physical quantity which cannot be measured directly. This is much like the absolute internal energy of a thermodynamic system or the so-called 'internal potentials' in a p-n junction or an interface between any two different metals. For the latter two examples it is well known that 'internal potentials' cannot be directly measured. Despite the inaccessibility of the internal pressure of a liquid, the transport of its particles would be expected to depend on it.

The external pressure in a liquid, if considered to be a thermodynamic quantity, as conventionally done, presents at least two serious conflicts. The first conflict lies within the domain of the kinetic theory. According to the latter, the pressure P should be defined according to the virial theorem. This particular assumption is used, for example, for gases and for electrons in solids, but not for liquids. The reason for this is that if P is calculated, for a liquid, it can be shown that, depending on the temperature, P could be orders of magnitude higher in the liquid than it would be in its vapour, in thermal equilibrium. Obviously this result represents a fundamental contradiction to the conventional criteria of thermal equilibrium. Despite this conflict, applying the kinetic theory to liquids is not discarded altogether. For example, the velocity distribution at room temperature is generally assumed to obey the Maxwell–Boltzmann statistics.

The other conflict may be explained on the basis of the material presented in section (5). In that section, it has been shown that $(-\mathrm{d}\mu)$ represents the work done per particle transported a distance $\mathrm{d}s$. If $\mathrm{d}P = 0$ in thermal equilibrium across the boundary of a liquid and its vapour, as conventionally assumed, then according to equation (16) at constant T, $\mathrm{d}\mu = 0$. This will be so anywhere within the boundary, and otherwise. If this conclusion were valid, it should be possible to transport particles from the liquid phase to the vapour phase at constant T without expending energy. This will mean that the latent heat of vaporization would be zero if the process occurred quasi-statically. This conclusion clearly is seriously contradicted by well-known observations.

The two conflicts just described may now be resolved through the new criteria of thermal equilibrium, and the fundamental new transport laws they are based on. The existence of the latent heat of vaporization is evidence that energy must be expended to transport particles quasi-statically from points in the liquid to points in the vapour at constant T. Thus by the definition of chemical potential introduced in section (5), $\mathrm{d}\mu \neq 0$ at points across the boundary between the two phases, at constant T. From equation (16), it follows inevitably that $\mathrm{d}P \neq 0$ across the boundary at constant T. This result was mentioned earlier to be an inevitable consequence of the virial theorem.

To explain this result further, one can imagine that the concentration n of the particles will vary across the boundary all the way from its value within the vapour n_v to that within the liquid n_l. It is conceivable that somewhere within the boundary, there exists a point Q at which n may be found to be (αn_v), where α is a number, let us say, less than 10. If the vapour pressure is sufficiently small, the phase at point Q will be gaseous, and the pressure at Q and at all points across the boundary between Q, and the uniform vapour, can then be calculated from equation (27). Therefore at Q, $P_Q = knT = k\alpha n_v T$. Thus, across the boundary at least within the gaseous portion of the transition region, it can be said that $\mathrm{d}P = kn_v T\mathrm{d}\alpha = 0$, in thermal equilibrium.

That static equilibrium can still occur at constant T, even when $\mathrm{d}P \neq 0$, is a matter already discussed phenomenologically in sections (4) and (7). In the latter section, it was concluded that in thermal equilibrium, and only then, $\mathrm{d}\mu$ must become necessarily an exact differential. This particular result was confirmed in section (7) to be the case for ideal boltzon and fermion particles. Since particles in most liquids, if not classical, would obey the Bose–Einstein statistics[24,25], it remains to be shown that, for such particles, $\mathrm{d}\mu$ is an exact non-vanishing differential in thermal equilibrium wherever $\mathrm{d}n \neq 0$.

To do so consider the Bose–Einstein function:

$$B(\varepsilon,\varepsilon_b) = \{\exp[(\varepsilon-\varepsilon_b)/kT] - 1\}^{-1} \qquad (36)$$

where ε_b represents the amount of energy measured from the Bose-level to the reference from which the energy ε is measured. It should be noticed that here ε_b is always a negative quantity. In this case the particle concentration and average kinetic energy per particle will be given respectively by:

$$n = \int_0^\infty g(\varepsilon)\, B(\varepsilon,\varepsilon_b)\, \mathrm{d}\varepsilon \qquad (37)$$

$$<\varepsilon> = (1/n)\int_0^\infty \varepsilon\, g(\varepsilon)\, B(\varepsilon,\varepsilon_b)\, \mathrm{d}\varepsilon \qquad (38)$$

It is now possible to formulate quantum-statistically the internal pressure in a liquid, the particles of which are bosons, on the basis of the virial theorem. This will be:

$$P = (2/3)n<\varepsilon> - P_0(n) = (2/3)\int_0^\infty \varepsilon\, g(\varepsilon)\, B(\varepsilon,\varepsilon_b)\, \mathrm{d}\varepsilon - P_0(n) \qquad (39)$$

Here $P_0(n)$ is the component of pressure contributed by the inter-particle forces. At constant T, this quantity may be expressed, at least in principle, by a Maclaurin's series in n.

If $g(\varepsilon)$ is assumed to be parabolic, then in view of (16), (36), (37) and (39), at constant T, it can be shown that:

$$\mathrm{d}\mu = \mathrm{d}\varepsilon_b - \mathrm{d}\varepsilon_0 \qquad (40)$$

Here $\mathrm{d}\varepsilon_0$ is an exact differential equal to $(1/n)\mathrm{d}P_0(n)$. From the definition of ε_b, it follows at once that in thermal equilibrium, $\mathrm{d}\mu$ is an exact non-vanishing differential for Bose liquids wherever $\mathrm{d}n \neq 0$. Obviously this conclusion is valid also for gases. This result explains the co-existence of the liquid and vapour phases when their particles are bosons.

(9) Diffusion in Isothermal Ideal Classical Liquids

This section presents the theory of diffusion in isothermal liquids on the basis of the new concept of liquid internal pressure, and the first generalized transport law.

Consider any isothermal liquid in which there are particles of another ideal Maxwell liquid. Let the concentration of these particles be non-uniform but time-independent.

According to the first generalized transport law, for positively charged particles, the current density is related to the driving force per particle, in any passive region near static equilibrium, by equation (4). For neutral particles, it is more appropriate to use the rate of particle flow $\mathbf{\Gamma}$ per unit area, rather than $\mathbf{J}$. In view of the Einstein mobility-diffusion relationship[26], and equation (4), $\mathbf{\Gamma}$ may be expressed by:

$$\mathbf{\Gamma} = (\mu'/q)n\mathbf{f} = (D/kT)\mathbf{f} \qquad (41)$$

For the situation under consideration, the quantity f is merely the diffusion force per particle. According to equations (19) and (20), at constant T, this force is given by:

$$\mathbf{f} = \mathbf{f}_t = \mathbf{f}_d = -(1/n)\nabla P \qquad (42)$$

From equations (27), (41) and (42), it follows that:

$$\Gamma = -D\nabla n \qquad (43)$$

Equation (43) will be recognized as what is generally called Fick's law[27]. It is interesting to notice that across a liquid–vapour boundary, $\nabla n \neq 0$, and in fact, ∇n is exceedingly high in thermal equilibrium. Notice here that, according to the first generalized transport law, equation (43) would not apply in that region. Rather, at constant temperature, the particles must be in static equilibrium.

FERROMAGNETISM AND COLOUR ZONING IN SOME MALAYAN CASSITERITE

By P. L. C. GRUBB and P. HANNAFORD

C.S.I.R.O. Mineragraphic Investigations, c/o Geology School, University of Melbourne, Parkville, N.2, and Department of Physics, University of Melbourne, Parkville, N.2, Victoria

LARGE cassiterite crystals from quartz-orthoclase-fluorite vein lodes at Pelepah Kanan, north-east Johore, possess conspicuous colour zoning and a small but strongly ferromagnetic fraction. From decrepitation tests it can be established that the mineral was formed at temperatures between 350° C and 360° C. Individual zones, which may be black, brown or colourless, range from a few microns to more than 1 mm in width. By reflected and transmitted light microscopy it is evident that the colour and ferromagnetic properties are not due to any resolvable foreign inclusions, nor are the refractive index and specific gravity values appreciably different. Furthermore, although a few weak anomalous lines exist which cannot be indexed as cassiterite, X-ray diffraction revealed no discernible difference between dark and colourless zones. Yet the dark ferromagnetic zones both here and in several samples from Thailand and Australia are found to possess slightly large 'a' unit cell parameters.

Chemical and spectrographic analyses of dark and colourless, strongly ferromagnetic and non-magnetic cassiterite fractions showed only slight compositional differences, which scarcely seem consistent with the properties of these fractions (Table 1). These analyses were confirmed by electron probe microanalyses, which showed no consistent relationship between the total iron content and colour of individual zones. Thermogravimetric analyses and Mossbauer spectra of the dark magnetic fraction, however, clearly ruled out the existence of any SnO which conceivably could be present as a separate phase.

Separation of crushed zoned cassiterite crystals into fractions of differing magnetic susceptibility showed that the dark brown or black fraction is the most ferromagnetic, having a susceptibility of 63×10^{-6} c.g.s., whereas the colourless variety is essentially non-magnetic. Thermal demagnetization analyses using a horizontal-type translation magnetic balance revealed two distinct inflexions which could both be interpreted as Curie points (Fig. 1). The second of these, at 580° C, can be assigned to magnetite, as confirmed by X-ray diffraction after completion of run. Furthermore, observations using hot-stage microscopy reveal that the dark ferromagnetic cassiterite crystals on heating to above 750° C become more translucent in appearance due to coagulation of the fine dispersion of stannate and/or magnetite particles. It appears, therefore, that the ferromagnetism arises from a second phase within the unheated cassiterite where it forms an extremely fine cloud-like dispersion which on heating to 380° C coagulates and reverts to magnetite. For reasons

Table 1. CHEMICAL ANALYSES OF CASSITERITE FRACTIONS FROM PELEPAH KANAN, NORTH-EAST JOHORE

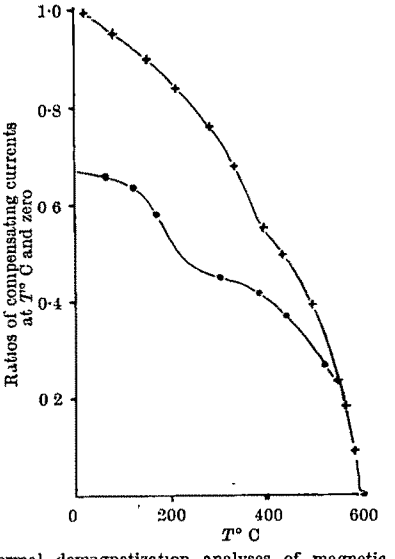

Fig. 1. Thermal demagnetization analyses of magnetic cassiterite from Pelepah Kanan. +, Heating, ●, cooling

to be discussed, this dispersed ferromagnetic phase is probably a ferrous stannate, and in support of this it is noteworthy that magnetite forms the chief decomposition product of the synthetic compound after calcining at 1,093° C (ref. 1). But by the same token considerable caution is required in examining cassiterite by electron diffraction techniques as the extreme temperatures to which specimens are necessarily subjected have been observed to have the same effect.

Owing to the difficulty of determining Fe^{2+} in cassiterite by direct chemical means, and in order to investigate further its magnetic character, Mössbauer spectra were obtained from dark ferromagnetic and light non-magnetic fractions using the 14·4 keV γ-ray of iron-57 and the 23·8 keV γ-ray of tin-119. Absence of observable magnetic splitting for both nuclei indicates that only small fractions of iron ($< \sim 10$ per cent) and tin ($< \sim 1$ per cent) atoms can be in a ferromagnetic or antiferromagnetic environment. This suggests that the ferromagnetism does not persist throughout a magnetic crystal but is localized in the minute domains already outlined.

The iron-57 Mössbauer spectra revealed quadrupole splittings and chemical shifts characteristic of Fe^{2+} and Fe^{3+} (Fig. 2). These spectra suggest that the magnetism and the coloration of the cassiterite are caused by a paramagnetic ferrous stannate which could be either $SnFeO_3$ or $SnFe_2O_4$.

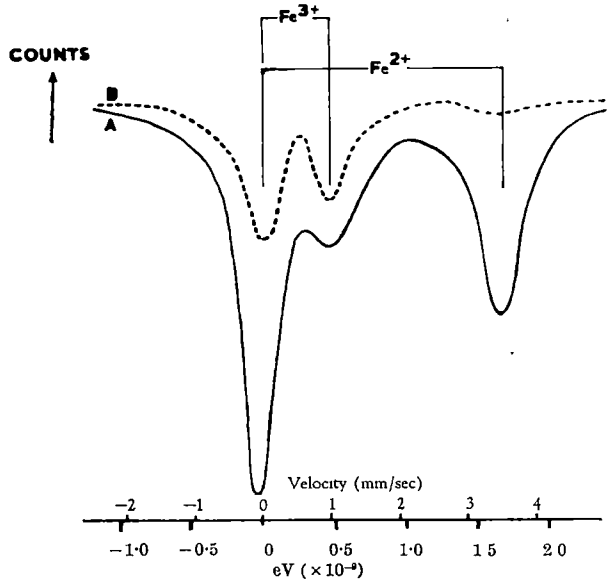

Fig. 2. Iron-57 Mossbauer spectra (relative to a 310 stainless steel source) for cassiterite (relative intensities for *A* and *B* not normalized). ——, Dark magnetic cassiterite; – – – –, colourless cassiterite

The crystal chemistry of Sn^{4+} and Ti^{4+} is not dissimilar, and it is suggested that the origin of ferromagnetism in cassiterite could be comparable to the behaviour of the solid solutions TiO_2–Fe_3O_4 or TiO_2–Fe_2O_3 (ref. 2). First in the TiO_2–Fe_3O_4 series, spinel-type titanomagnetites having the general formula $Ti_mFe_{3-m}O_4$ are derived from magnetite Fe_3O_4 by the substitution of Ti^{4+} for Fe^{3+} ions together with a change of ionization of an Fe^{3+} ion to Fe^{2+}. As m increases, the molecular saturation moment and Curie point (4 μ_B and 578° C for magnetite) fall regularly as the unbalancing of magnetic moments decreases, and for $m = 1$ ($TiFe_2O_4$, ulvöspinel), the phase becomes paramagnetic. Although this system provides a possible explanation for the origin of the magnetism in cassiterite, the absence of any detectable magnetite or tin analogue of titanomagnetite in the fresh magnetic cassiterite, together with the relatively low susceptibilities of titanomagnetite analogues in the region of $TiFe_2O_4$ compared with the overall susceptibilities of the magnetic cassiterite fractions, has led us to prefer the second alternative. In this, the rhombohedral series $Fe_{2-m}Ti_mO_3$ has end members haematite Fe_2O_3 and ilmenite $FeTiO_3$, which are both antiferromagnetic; but near the composition $Fe_{4/3}Ti_{2/3}O_3$, it is possible to obtain considerable unbalancing of magnetic moments between neighbouring cation layers, so that the compound is strongly ferromagnetic with a molecular saturation moment of about 2 μ_B and a Curie point of 150° C. Nagata[3], moreover, has shown that if the alternating cation layers had compositions $(\overrightarrow{Ti^{4+}_{1/6}Fe^{2+}_{1/6}Fe^{3+}_{2/3}})$ and $(\overleftarrow{Fe^{2+}_{1/2}Ti^{4+}_{1/2}})$, this would give the required molecular moment (arrows represent directions of magnetic moments). Now for cassiterite, the apparent correlation between the ferromagnetic character and the ferrous ion content would favour a tin analogue of $Fe_{4/3}Ti_3O_{2/3}$, since this would more likely be found interspersed in a matrix of the ferrous compound than would a counterpart of titanomagnetite. This conclusion is of course based on the (probable) assumption that $SnFeO_3$ is paramagnetic.

We thank Dr. A. D. Wadsley of the C.S.I.R.O. Division of Mineral Chemistry, and Prof. J. M. Cowley of the Department of Physics, University of Melbourne, for their advice. Special thanks are also due to Dr. L. G. Parry of the Department of Physics, University of New South Wales, for obtaining the thermal demagnetization analyses, and to Dr. J. Sanders of the C.S.I.R.O. Division of Tribophysics for taking several electron diffraction patterns. For conducting one of us over the deposit and beneficiation plant we also thank the mine manager and staff of the Pelepah Kanan Tin Mine.

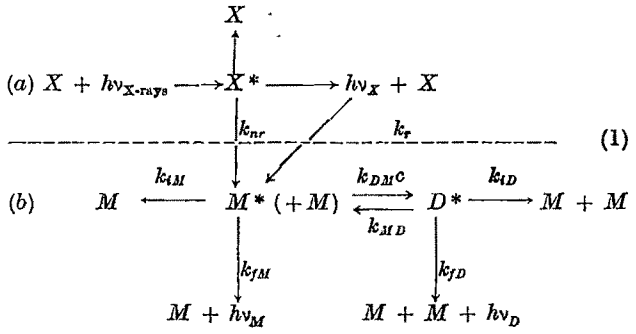
EXCIMER X-RAY INVESTIGATION



By Dr. L. G. CHRISTOPHOROU* and J. G. CARTER
Health Physics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

THE monomer-excimer emission spectra of pyrene in solution[1,2] and of 2-ethyl and 1 : 2-dimethyl naphthalene in the liquid phase[3], excited by ultra-violet light, were reported previously. Birks *et al.*[4] have also used phosphorus-32 β-radiation to excite a 10^{-3} M solution of pyrene in toluene and reported identity of photofluorescence and scintillation spectra. In this article we investigate the excimer formation in solutions and in pure liquids under X-ray excitation and we determine the binding energy of excimers formed in organic liquids.

* Department of Physics, University of Tennessee, Knoxville, and Oak Ridge National Laboratory, Oak Ridge, Tennessee.

Solutions. Oxygen-free solutions of pyrene in *cyclo*hexane were excited at room temperature by 230-keV X-rays. The relative quantum intensities, I_λ, were measured by a Bausch and Lomb 500-mm grating monochromator for various solute concentrations, c, and are plotted in Fig. 1. The spectra are normalized at a fixed wave-length $\lambda = 410$ mm, as were the photofluorescence spectra[2]. The shape and position of the monomer-excimer bands are identical to those obtained under ultra-violet excitation. The ratio of the excimer quantum yield, I_D, to that, I_M, of the monomer, I_D/I_M, varies linearly with c up to at least 10^{-2} M.

If X and M are the solvent and solute molecules, respectively, and D^* is the excimer, then we may consider the following two-step process:

In step (*a*) we consider only the species X^*, a solvent molecule in its lowest excited singlet state, from which electronic excitation energy is transferred to M radiatively and non-radiatively with rate constants k_r and k_{nr}, respectively. In step (*b*), which is the case of normal fluorescence (that is, only monomers are initially excited), k_{fM}, k_{tM}, k_{fD}, k_{tD}, $k_{DM}c$ and k_{MD} are the rate parameters for M fluorescence, M internal quenching, D^* fluorescence, D^* internal quenching, D^* formation, and D^* dissociation, respectively. Thus, if it is assumed that X is initially excited and that M is afterwards excited by energy transfer from X, the formation and emission of D^*, and the emission of M^*, which follow M^* formation, should be independent of the mode of excitation of X. Considering the kinetics of step (*b*), we have ($c \leqslant 10^{-2}$ M):

$$\frac{I_D}{I_M} = \frac{k_{fD}\, k_{DM} c}{k_{fM}(k_{fD} + k_{tD} + k_{MD})} = Kc \qquad (2)$$

For pyrene oxygen-free solutions in *cyclo*hexane, K is found equal to 640 mole l.$^{-1}$ and is independent of X-ray energy E_X (120 keV–240 keV) and/or X-ray intensity I_X (5 m.amp–20 m.amp). This value for K is $\sim$4 times smaller than that obtained under ultra-violet excitation (= 2,500 mole l.$^{-1}$) of the same system[4]. For pyrene oxygen saturated solutions in *cyclo*hexane, K is again smaller (500 mole l.$^{-1}$) for X-ray excitation than its value under ultra-violet excitation[2] (1,110 mole l.$^{-1}$) by a factor of $\sim$2·2.

The rate parameters k_{DM}, k_{MD}, and k_{tD} in equation (2) were found[6] to depend on the temperature, T, the solvent X, and the solute M, while k_{fM} and k_{fD} were found to be a function of the refractive index, n, of the solvent (increase with n) and independent of T. T, X and M were the same for ultra-violet and X-ray excitation.

Ion recombination of the solute which results in a higher population of triplets than singlets (thus affecting K) is not likely to be important in these experiments, where the energy absorbed directly by M is negligible.

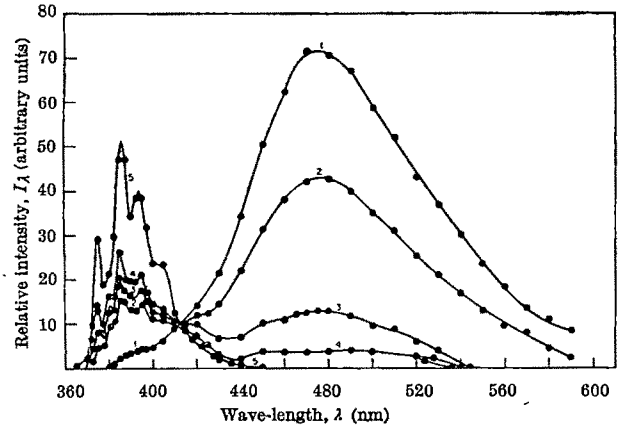


Fig. 1. Emission spectra of pyrene in *cyclo*hexane (oxygen-free solutions). Curves (1) 10^{-3} M; (2) 5×10^{-3} M; (3) 10^{-4} M; (4) 5×10^{-4} M; (5) 10^{-4} M

Oxygen-free solutions of 1 : 2-dimethyl naphthalene in *n*-heptane at various c were also excited by X-rays and a value of 0·46 mole l.$^{-1}$ was calculated for K. This is smaller by a factor of $\sim$ 1·7 than that (0·78 mole l.$^{-1}$) reported[7] for excitation of the same system by ultra-violet light. For this molecule at room temperature, $k_{MD} \gg k_{fD} + k_{tD}$ (see Figs. 2 and 3 and ref. 7) and thus equation (2) can be written:

$$\frac{I_D}{I_M c} = K = \frac{k_{fD}}{k_{fM}} \frac{k'_{DM}}{k'_{MD}} e^{B/kT} \qquad (3)$$

where B is the excimer binding energy and k is Boltzmann's constant. The entropy change ΔS of the system is determined by the ratio k'_{DM}/k'_{MD} and is a property of M independent of T (ref. 6). The differences in the excimer binding energy, B, for ultra-violet and X-ray excitation are within the experimental error. B is more likely to be unchanged for the two modes of excitation and the changes in K (for the two modes of excitation) are attributed to additional quenching of D^* by species formed by the ionizing radiation. It is worth noting that Berlman[8], who used a pulsed beam of electrons of 75-keV energy to excite a $\sim 2{\cdot}5 \times 10^{-3}$ M solution of pyrene in deoxygenated *cyclo*hexane, reported monomer and excimer decay times which differ appreciably from those reported by Birks, Dyson and Munro[5], who used ultra-violet light to excite the same system ($c = 2{\cdot}5 \times 10^{-3}$ M).

Fig. 1 and equation (2), however, indicate that excimers are formed subsequent to M^* formation by collision of M and M^* as suggested by Birks *et al.*[4], the process being collision controlled. It should be pointed out that triplet–triplet annihilation resulting in the formation of D^* and M^* (that is, initial formation of D^* and M^*) which is responsible for the delayed fluorescence[10] can be neglected here.

Liquids. In the liquid state of a compound, only stage (*b*) of process (1) need be considered, that is, M is excited directly by the ionizing radiation. The scintillation spectra of liquid 2-ethyl naphthalene at various temperatures (25°–142·5° C) are presented in Fig. 2. Similar spectra were obtained for liquid 1 : 2-dimethyl naphthalene for the same temperature range. Our scintillation spectra at 25° C agree well with the photofluor-

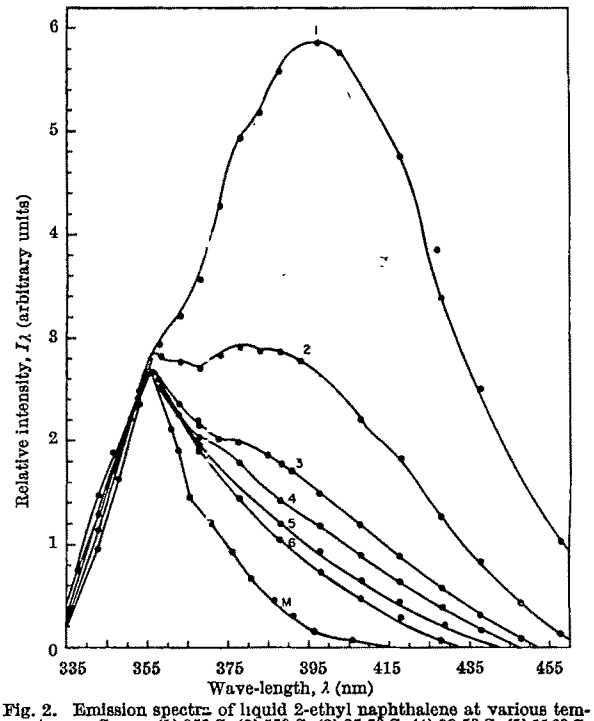

Fig. 2. Emission spectra of liquid 2-ethyl naphthalene at various temperatures. Curves (1) 25° C, (2) 55° C; (3) 85·5° C; (4) 98·5° C; (5) 116° C; (6) 142·5° C; (*M*) normalized monomer emission (solution)

escence spectra reported by Birks and Aladekomo[3]. In the case of 2-ethyl naphthalene, both the photofluorescence and scintillation spectra show a small amount of residual monomer which is more pronounced in the scintillation spectrum. As temperature increases, the excimer emission decreases and the monomer emission becomes more pronounced due to the dissociation of D^* (ref. 9). This is clearly demonstrated in Fig. 2, where curve M represents the normalized emission spectrum of M in solution (suitably shifted towards longer λ).

From equation (3), which applies also to pure liquids, B can be obtained from the slope of the $\log_{10} I_D/I_M$ versus T^{-1} curves. In Fig. 3 the observed temperature dependence of the emission spectra of liquid 2-ethyl naphthalene are plotted as $\log_{10} I_D/I_M$ versus T^{-1}. From the slope of these curves, we have calculated a binding energy equal to 0·27 eV for 2-ethyl naphthalene. A binding energy of 0·28 eV is calculated for 1 : 2-dimethyl naphthalene. For solutions excited by ultra-violet light, Aladekomo and Birks[7] have recently reported a binding energy of 0·29 ± 0·02 eV for 2-ethyl naphthalene and 0·31 ± 0·03 eV for 1 : 2-dimethyl naphthalene. They also reported identical values for the binding energy of 1 : 6-dimethyl naphthalene in solution and in the liquid state of the compound.

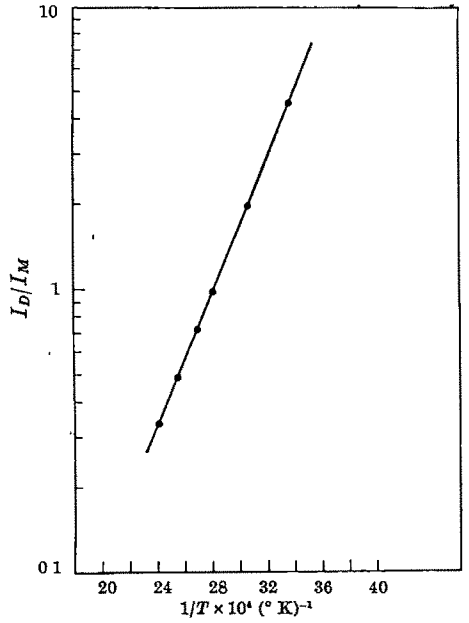

Fig. 3. Liquid 2-ethyl naphthalene I_D/I_M versus $1/T$

In conclusion, excimers in pure liquids and in solutions are formed subsequent to M^* formation by collision of M^* and M, independently of the mode of excitation. The shape and position of the monomer-excimer emission are unaffected by the mode of excitation, but the excimer-monomer quantum yield is not. The excimer binding energy for naphthalene derivatives appears to be the same for solutions and pure liquids and unaffected by the mode of excitation. From our results and the results of others[6,7] on the temperature dependence of the emission spectra of pure liquids it is also suggested that since excimers are more easily formed in pure liquids than in solutions, and since B seems to be environment independent, the excimer binding energy can be measured more easily by heating a compound in the liquid state than by cooling or heating it in a solution (where problems of solubility on cooling and solvent boiling on heating arise).

This work was sponsored by the U.S. Atomic Energy Commission under contract with the Union Carbide Corporation.

Note added in proof. If we assume that the smaller value of the ratio I_D/I_M under X-ray excitation (as compared with its value under ultra-violet light excitation) is due to the presence of a quencher, Q, produced by the ionizing radiation, then equation (2) becomes:

$$\frac{I_D}{I_M} = \frac{k_{fD}\, k_{DM} c}{k_{fM}\,(k_{fD} + k_{iD} + k_{MD} + k_{QD}[Q])} \qquad (4)$$

Using equations (2) and (4) and taking into consideration our finding that I_D/I_M is independent of I_X and E_X within the region stated, we calculated k_{QD} for pyrene in *cyclo*-hexane from two independent sets of data: (i) from values of I_D/I_M for oxygen-free solutions excited by X-rays and ultra-violet light, and (ii) from values of I_D/I_M for oxygen-saturated solutions excited by X-rays and ultra-violet light. In both cases we obtained $k_{QD} = 6{\cdot}3 \times 10^7$ sec^{-1}.

INVESTIGATION OF RAUSCHER VIRUS RIBONUCLEIC ACID

By F. GALIBERT, C. BERNARD, PH. CHENAILLE and Prof. M. BOIRON
Laboratoire d'Hématologie Expérimentale, Institut de Recherches sur les Leucémies, Hôpital Saint-Louis, Paris

WE recently reported[1] that high molecular-weight RNA (70 $S_{20,w}$) could be extracted from Rauscher leukaemia virus. The results of further investigations of the properties of this RNA are reported here.

Rauscher virus was produced *in vitro* by the chronically infected cell line *JLS V5* (ref. 2). The cells were cultivated in a medium made of casein hydrolysate in a phosphate buffer plus 15 per cent calf serum, and were seeded in aliquots of 10^7 cells in 1-l. Roux bottles. After a delay of 6 h the medium was changed and replaced with casein hydrolysate in *tris* (*tris* hydroxymethyl-aminomethane) buffer plus 10 per cent foetal calf serum, containing 5 μc. phosphorus-32 per ml. In some experiments, we used a double labelling with phosphorus-32 (at the same ratio) and algal hydrolysate protein-^{14}C (0·25 μc./ml.). The medium was changed after 3 days of incubation at 37° C; 24 h later, culture supernatants were collected and purified according to Moloney's technique[3]. The presence of virus in the final pellets was verified by electron microscopy and by inoculation of *BALB/c* mice. As controls, supernatants from non-infected *JLS V6* cell line cultures previously labelled with phosphorus-32 were submitted to the same process.

The labelled viral pellets, supplemented with unlabelled *JLS V5* cells (used as a carrier), were homogenized in 10^{-2} M sodium acetate buffer *p*H 5·1 plus 2 μg/ml. polyvinylsulphate (PVS). Following this procedure, 0·4 per cent of sodium dodecyl sulphate was added. The deproteinization was achieved by three phenolic treatments (one for 30 min with an equal volume, and two for 15 min with half volumes) at 4° C with water-saturated phenol, freshly distilled under low pressure. The RNA was precipitated with absolute ethyl alcohol in the presence of 0·1 M sodium chloride for 2 h at −10° C, washed with 67 per cent ethyl alcohol to eliminate the phenol and dissolved in 10^{-2} M acetate buffer *p*H 5·1 with 0·1 M sodium chloride.

The RNA solution was layered on top of a linear sucrose gradient (5–20 per cent w/v in acetate–sodium chloride buffer) and centrifuged in a 'Spinco *SW* 25' swinging-bucket tube. The sedimentation constant of the different RNA fractions was determined by the method of Martin and Ames[4]. A fractionation was also performed by chromatography on a methylated albumin column (MAK) according to the technique of Mandell and Hershey[5].

The base composition was achieved by the method of Katz and Comb[6] using the high molecular-weight RNA peak which was isolated in a sucrose gradient, dialysed against 10^{-3} M sodium chloride, lyophilized and hydrolysed for 20 h at 37° C with 0·3 N potassium hydroxide. The potassium hydroxide was neutralized by perchloric acid and potassium perchlorate was eliminated by centrifugation. The radioactivity in the different fractions was evaluated in a gas flow counter, after drying the planchets.

Isolation of a viral RNA with a high sedimentation constant. After a centrifugation at 20,000 r.p.m. for 15·5 h in a sucrose gradient, the following fractions were obtained (Fig. 1): by optical density three peaks were visible corresponding to the cellular RNAs of the *JLS V5* cells (28*S*, 18*S* and 4*S*) and by radioactivity two peaks, one ('light' RNA) being located at the 4*S* area, the other at the bottom of the tube. Both peaks were RNase-sensitive (50 γ/ml.).

After centrifugation at 25,000 r.p.m. for 2·5 h in a sucrose gradient (Fig. 2), the radioactivity which was previously located at the bottom of the tube constituted a well-defined peak with a sedimentation constant of about 70 $S_{20,w}$ ('heavy' RNA). All other RNA fractions remained on the top of the tube under these conditions of centrifugation. In a similar experiment with an extract from uninfected control *JLS V6* cell line culture supernatants, no peak in the 70*S* region could be detected.

Using methylated albumin column chromatography, two peaks were detected eluting respectively at 0·40 and 0·95 sodium chloride molarities (Fig. 3), in addition to unlabelled peaks of *JLS V5* cell RNAs.

Characterization of the heavy viral RNA. Such a heavy RNA fraction brings up the question as to whether the material might be a ribonucleoprotein or an aggregate. The conditions of extraction do not favour the preservation of a ribonucleoprotein-like structure. In order to exclude this eventuality, a double-labelling experiment was undertaken in which viral RNA was labelled with phosphorus-32 and viral proteins with carbon-14 (algal hydrolysate). Virus pellets were obtained by Moloney's method and divided into two aliquots; one of them was phenol-treated as above and RNA isolated by sucrose gradient, the other was purified with two consecutive centrifugations in a caesium chloride density gradient[7].

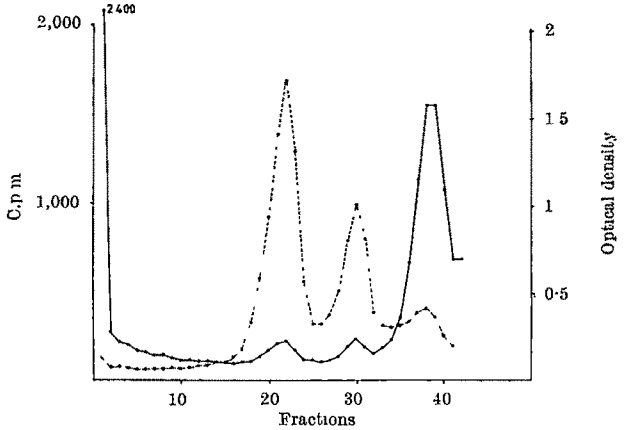

Fig. 1. Sedimentation in sucrose gradient 5–20 per cent (15·5 h, 20,000 r.p.m. in 10^{-2} M acetate, 10^{-1} M sodium chloride, *p*H 5·1) of RNA extracted from *JLS V5* cells o---o---o---o, and from the phosphorus-32 labelled viral pellet •—•—•—•, purified by Moloney's technique. The bottom tube was punctured and eight-drop samples collected to measure absorption at 2600 Å and the radioactivity in 5 per cent trichloroacetic acid precipitates

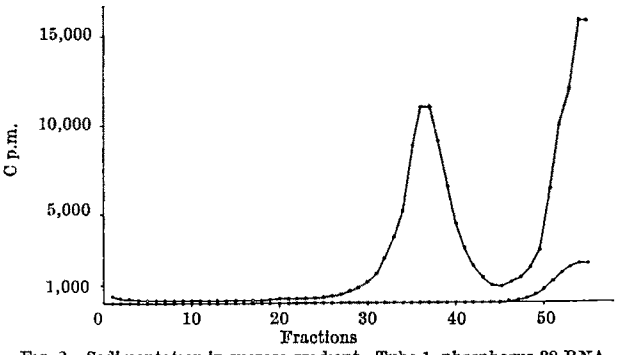

Fig. 2. Sedimentation in sucrose gradient Tube 1, phosphorus-32 RNA extracted from culture, supernatants of *JLS V5*, o---o---o---o. Tube 2, phosphorus-32 RNA extracted from culture supernatants of *JLS V6*, •—•—•—•. Running for 2·5 h at 25,000 r.p.m. Drop collection and radioactivity were made as described in Fig 1

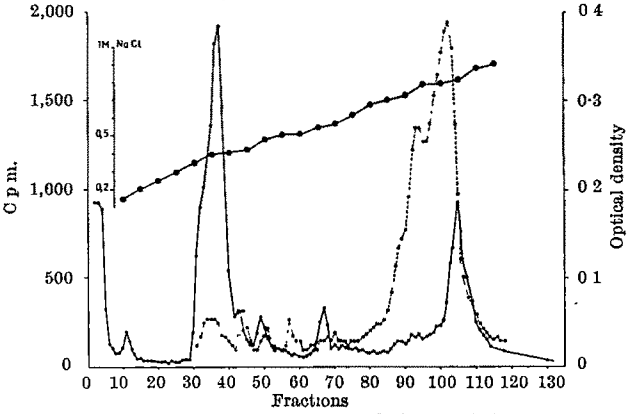

Fig. 3. Extract as in Fig. 1 chromatographed on methylated albumin column (MAK). Elution gradient from 0·2 M to 1·2 M sodium chloride phosphate buffer *p*H 7; 2·5 ml. per tube. •—•—•—•, Optical density, o----o----o, radioactivity

Both virus band and viral RNA were therefore analysed for phosphorus-32 and carbon-14 radioactivity. The results of two experiments appear in Table 1. The carbon-14 radioactivity is present in the virus and absent from the heavy RNA peak, thus excluding the possibility that this peak is a ribonucleoprotein.

Though the homogeneity and exact symmetry of the 70*S* RNA peak made it unlikely that it was a structure aggregated either by means of metallic ions or other non-covalent bonds, it was necessary to exclude this eventuality by the following experiments: RNA extraction was performed in 10^{-2} M EDTA, *p*H 7, plus PVS 2 μg/ml. Following isolation in a sucrose gradient, an RNA peak identical with the one characterized under standard conditions was obtained. Moreover, viral RNA dialysed at 4° C against solutions of various ionic strengths modified only to a small extent its sedimentation constant, as shown in Table 2. Persistent presence of the 70*S* RNA following EDTA treatment as well as in solutions with very low ionic strength indicated that this peak did not consist of an aggregated structure.

Base composition. The 70*S* peak base composition was determined for several preparations. The results are shown in Table 3. The base composition of the light RNA does not appear in the Table since it varies from preparation to preparation. These variations are probably due to very small components which were lost during the purification of this fraction, and particularly during dialysis

Table 1

Radioactivity (c.p.m.)	Virus purified by Moloney's method		Virus purified in caesium chloride gradient		Viral RNA	
Phosphorus-32	1,000	1,000	1,000	1,000	1,000	1,000
Carbon-14	167	121	170	140	0	0

against 10^{-3} M sodium chloride. Moreover, degraded cellular RNAs, however small their proportion may be in that peak, cannot be eliminated.

RNase sensitivity. 70*S* viral RNA was submitted to various RNase (Nutritional Biochemical Corporation) concentrations, ranging from 10 γ/ml. to 0·1 γ/ml. The results appear in Table 4. In all cases, a high degree of RNA degradation was observed. However, it was never complete, and about 7 per cent of the radioactivity remained precipitable by trichloroacetic acid (TCA).

In conclusion, the extraction of RNA from labelled Rauscher virus leads to the isolation of two radioactive fractions, one light (~4–5*S*) and the other heavy (~70*S*). These two fractions are always present, but their relative amount varies from experiment to experiment; since they are RNase sensitive and under the conditions of extraction, a completely deproteinized RNA is currently obtained, they are made of RNA. The 'light' fraction is of viral origin, since cellular RNAs are poorly labelled, as shown in Fig. 1. However, the presence of cellular RNAs (transfer RNA or degraded ribosomal fragments) cannot be excluded in this peak, as suggested by the results of extraction from uninfected *JLS V6* cells (Fig. 2). The size of this light component is too small to represent the intact viral RNA. It may represent either its product of degradation[8] or, eventually, sub-units of the viral RNA. On the contrary, the heavy fraction probably represents intact viral RNA for the following reasons: viral pellets were used for extraction and the low radioactivity found in ribosomal RNAs indicates the good quality of the purification achieved by Moloney's technique; the RNA extracted from uninfected cell culture supernatants did not give such a peak; finally, a 70*S* peak identical with that produced by the virus concentrated according to Moloney's technique was obtained following centrifugation in a caesium chloride gradient (which is known to yield an excellent virus purification). On the other hand, the possibility that the 70*S* component represents a ribonucleoprotein or an aggregate seems to be excluded. A ribonucleoprotein is unlikely because (*a*) double labelling experiments do not reveal protein and (*b*) it can be chromatographed on MAK, whereas a ribonucleoprotein would become irreversibly attached to the kieselguhr. An aggregate seems to be excluded by the results of extractions performed in the presence of EDTA and by the behaviour of the 70*S* fraction in the presence of low ionic strength solutions.

Another problem raised by this heavy fraction is that of its single or double-stranded structure. The results of base composition determinations, particularly the study of the ratios G/C and A/T, are not conclusive, but the very high sensitivity of 70*S* RNA to RNase (the significance of the small RNase-resistant fraction of the viral RNA is still unknown) is in favour of a single-stranded structure. Moreover, if such a molecule was double-stranded (*a*) it would have such a rigidity that it would be scarcely extractable without any mechanical rupture, and (*b*) its estimated molecular weight would be inconsistent with the amount of RNA reported in the related Rous sarcoma and avian myeloblastosis viruses[9,10].

These facts seem to indicate that Rauscher virus RNA is single-stranded, and its molecular weight value calculated by Spirin's expression[11] would be about 10^7. This value is close to what has recently been reported by Robinson *et al.*[12] for Rous sarcoma virus, by Harel *et al.*[13] for avian myeloblastosis virus, and by Duesberg *et al.*[14] for Newcastle disease virus. Recently, Mora *et al.*[15] have shown that the RNA extracted from the highly infectious plasma Rauscher virus is a single-stranded molecule of about 13×10^6 molecular weight. Further experiments are in progress to investigate the structure of this viral RNA. It can only be said at the present time that its behaviour under various ionic strengths at 20° C seems to be different from that of tobacco mosaic virus[16] and Rous sarcoma virus[12] RNAs.

LARYNGEAL MYOTATIC REFLEXES

By Dr. M. A. ABO-EL-ENEIN* and Dr. BARRY WYKE†

Neurological Laboratory, Department of Applied Physiology, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2

In the course of an examination of the proprioceptive reflex innervation of the larynx, previous investigations[1–6] in this laboratory revealed the existence of articular reflexes in the larynx. These reflexes, driven by low-threshold, rapidly adapting corpuscular mechanoreceptors embedded in the capsules of all the laryngeal joints[1,2,5,6], produce transient, reciprocally related changes in the tone of the intrinsic laryngeal muscles[3,4,6] whenever the laryngeal joints are moved in appropriate directions[3–6]. The afferent impulses evoking these articular reflex responses in the laryngeal muscles are conducted rapidly into the brain stem in large diameter, myelinated afferent fibres in the laryngeal branches of the vagus nerves[2,3,5,6] —by way of the ipsilateral internal laryngeal nerve in the case of the thyrohyoid, thyro-epiglottic and cricoarytenoid joints[1,2,6], and by way of the ipsilateral recurrent laryngeal nerve in the case of the cricothyroid joint[1,2,4–6]—from which they are polysynaptically relayed to the motoneurone pools of the laryngeal muscles[4–6].

These articular reflexes, however, are essentially phasic in character, producing transient adjustments in the tone of the laryngeal muscles only at the moment of joint displacement[4–6]. The laryngeal articular mechanoreceptors thus have no sustained influence on the tone of the laryngeal muscles[6]—yet, in view of the precisely regulated,

* On leave from the Department of Anatomy, Al Azhar University, Cairo.

continuous adjustments of laryngeal muscle tone that occur unconsciously during the respiratory cycle and during phonation[6-9], a tonic proprioceptive reflex system must be present in the larynx[1,6,13-15]. Such a reflex system would require to be driven by very slowly adapting mechanoreceptors located in the larynx; and as appropriate receptors are almost entirely lacking in the laryngeal joints[2-6], we have examined the laryngeal muscles neurohistologically and neurophysiologically for evidence of the presence therein of slowly adapting mechanoreceptors capable of provoking sustained alterations in the tone of the intrinsic muscles.

Previous attempts to demonstrate such reflexes in the intrinsic muscles of the larynx in various species of animals, and in man, have either been unsuccessful[10-13] or, at best, equivocal in their results[14,15]. This is in spite of the fact that histological investigations in man, and in some animals, have suggested that certain of these muscles contain nerve endings the structure and location of which might qualify them as slowly adapting mechanoreceptors[13,16-19]. This article reports our identification of sustained laryngeal myotatic reflexes, distinct from the phasic articular reflexes that we have previously described[3-6], that are provoked from mechanoreceptors located within the intrinsic muscles of the larynx. (A later communication will describe the structural features of the receptor endings in the laryngeal muscles that we believe to be responsible for the tonic laryngeal myotatic reflexes reported here.)

Experiments were performed on twelve neurologically intact, adult cats (average weight 3·8 kg) under light, controlled (monitored) pentobarbitone anaesthesia. In eight experiments tracheostomy was not performed, and the animals were allowed to breathe an oxygen-enriched air mixture spontaneously through an intrapharyngeal tube so that air flowed in and out through the larynx in the normal manner during the respiratory cycle: in this way, the influence of the myotatic reflexes on the oscillations of laryngeal muscle tone during the various phases of the respiratory cycle could be examined. In four experiments a low tracheostomy intubation was performed, so that the same gas mixture was breathed spontaneously in the absence of air flow through the larynx, thereby enabling the influence of the myotatic reflexes to be examined in the absence of respiratory oscillations in laryngeal air pressure. The pulmonary ventilation rate, tidal volume and laryngeal resistance to air flow were monitored continuously from meters on a small-volume Drager 'Anaesthesia-Spiromat' machine, through which the animals breathed. (The 'Anaesthesia-Spiromat' was provided by the Department of Anaesthetics of the Royal College of Surgeons of England, through the courtesy of Dr. Denis Hill.)

The animals were kept warm on a thermostatically regulated, heated operating table, and were supplied with isotonic fluid through a cannula in the right femoral vein that was also used for administration of the anaesthetic agent. Operating procedures on the larynx were performed with microsurgical instruments and a Zeiss operating microscope. Throughout each experiment, all exposed tissues were submerged in a pool of warm mineral oil.

The larynx was exposed through a mid-line anterior cervical incision. After removing the extrinsic muscles on the left side, the left lamina of the thyroid cartilage was exposed, and the laryngeal nerves were identified on both sides. After freeing it from the inferior constrictor muscle and the internal laryngeal nerve (which was preserved intact), the left thyroid ala was removed up to the mid-line—except for a small vertical fragment to which the anterior end of the left thyro-arytenoid (vocalis) muscle remained attached, and a thin horizontal strip to which the upper border of the left cricothyroid muscle was left attached. These two cartilaginous strips were separated from one another, and from the remainder of the thyroid cartilage, so that they could be moved independently. Possible adventitious reflex effects from movement of the left cricothyroid joint[3-6] were precluded by disarticulating it, after dividing the inferior cornu of the thyroid cartilage and freeing the attachment of the cricothyroid muscle to the joint capsule. The lumen of the larynx was not opened at any stage. The crico-arytenoid joints, and their muscular attachments, were left intact to provide a source of articular reflexes for control purposes during traction on the laryngeal muscles attached to the arytenoid cartilages. The animals were immobilized in the supine position by fixation to a brass scaffold bolted to the operating table.

Non-elastic traction threads were attached to the cartilaginous strip along the upper border of the left cricothyroid muscle, to the cartilage fragment at the anterior end of the left thyro-arytenoid (vocalis) muscle, to the rostral end of the right sternothyroid muscle (after freeing it from its thyroid attachment), and to the proximal cut end of the left patellar tendon. The threads were passed over pulleys attached to the fixation scaffold, and graduated passive stretch was applied to each muscle in turn for varying periods through the threads, with the aid of weights ranging from 3 g to 25 g. The pulleys and threads were orientated so that traction was applied to the left cricothyroid and right sternothyroid muscles in a caudal-rostral plane, and to the left thyro-arytenoid (vocalis) muscle in a postero-anterior plane; traction was applied to the left patellar tendon in the proximo-distal plane of the leg.

Pairs of fine, stainless-steel recording electrodes (insulated except at their tips) were inserted into the left and right cricothyroid, left thyro-arytenoid (vocalis), right sternothyroid and left rectus femoris muscles in every experiment. In some experiments, additional pairs of electrodes were inserted into the right thyro-arytenoid (vocalis) muscle (after removing part of the right thyroid ala) and into the left lateral and posterior crico-arytenoid muscles (after rotating the larynx to the right). Electromyograms were recorded simultaneously from all the muscles on a Grass polygraph, together with records of the animal's respiratory movements in thorax and abdomen, and of its electrocardiogram. Recordings were run in the absence of stretch of the muscles to examine their resting activity; and continuously before, during and after the application of each stretch to each muscle, the procedure being repeated at least three times in each instance.

The effects of varying degrees of general anaesthesia on the resting activity and on the stretch responses of each of the muscles were then examined, as were the effects of serial division of each of the laryngeal nerves (internal, external, superior, recurrent, ramus communicans) on the two sides—in different sequences in different experiments.

Two types of myotatic reflex response were demonstrated in the laryngeal muscles during their passive stretch—one facilitatory and the other inhibitory. As with the laryngeal articular reflexes[4-6], these myotatic reflexes could only be elicited in the early stages of barbiturate anaesthesia: they were entirely absent at the stages of general anaesthesia customarily used for major surgical procedures.

Facilitatory myotatic reflexes. These reflexes were evidenced by a sustained increase in the amplitude and frequency of motor unit discharge in the stretched muscle that began as soon as the stretch was applied, persisted throughout its application (for periods of up to 3 min), and disappeared as soon as the stretch was removed. The threshold stretch tension required for the production of such responses in the cricothyroid and thyro-arytenoid muscles was 5 g; and the magnitude of the response progressively increased with increments in the degree of stretch, up to 15 g. But further increases in stretch tension beyond 15 g (up to 25 g) converted the facilitatory response into an inhibitory reflex response (*vid. inf.*),

evidenced by a sustained decrease in the amplitude and frequency of motor unit discharge in the stretched muscle. The threshold tension for elicitation of the facilitatory response in the sternothyroid muscle was a little lower (3 g) than in the intrinsic muscles; and the degree of stretch required to convert the facilitatory response into an inhibitory response was higher (in excess of 20 g).

Stretch applied either to the left cricothyroid or left thyro-arytenoid muscle was usually accompanied by equally sustained changes (either facilitatory or inhibitory) in the motor unit activity of other muscles on the same and on the opposite sides of the larynx, in patterns that varied with the degree of stretch and with the particular muscle being stretched. (These synergistic and reciprocal myotatic reflexes will be described in more detail in a later communication.)

An additional facilitatory reflex effect was usually associated with application of stretch to the left thyro-arytenoid muscle, in that at the moment of application of the stretch (and also at the moment of its removal) a brief (less than 1 sec) high-amplitude burst of motor unit potentials was evoked in the stretched muscle, and (at lower amplitude) also in the ipsilateral cricothyroid muscle. These bursts of activity occurred only at the beginning and end of each sustained stretch reflex response, and increased in amplitude and duration (up to 1 sec) with increasing degrees of stretch—irrespective of whether the myotatic reflex response evoked thereby was facilitatory or inhibitory. These 'on–off' transients have all the characteristics of the laryngeal articular reflex responses described previously[3–6], and were selectively abolished by section of the ipsilateral internal laryngeal nerve (which innervates the crico-arytenoid joint[1,2,6]. It is clear, then, that they are superimposed phasic reflex responses to stimulation of the rapidly adapting mechanoreceptors located in the capsule of the crico-arytenoid joint[1,2,6], resulting from movement of the arytenoid cartilage when tension is applied to, or removed from, the anterior end of the thyro-arytenoid muscle—the posterior arytenoid attachment of which is deliberately left intact in these experiments.

In those experiments in which the animal was breathing through its larynx, cyclical fluctuations in the tone of the laryngeal muscles were conspicuous in the alternating phases of respiration (they were usually absent, or barely apparent, in the tracheotomized animals). Sustained application of stretch to the cricothyroid or thyro-arytenoid muscles in these circumstances produced greater reflex effects on motor unit activity in the resting than in the active phases of the respiratory cycle. Further, the degree of stretch necessary for the production of observable effects during the active phase was substantially greater than that needed during the resting phase; and often, no facilitation of the active phase could be observed in circumstances when there was marked facilitation of activity during the resting phase. This is in marked contrast to the situation in the tracheotomized animals, in which reflex facilitation was evenly sustained throughout the period of stretch without respect to the respiratory cycle, and indicates that the myotatic reflex response to passive stretch is depressed or aborted by active contraction of the stretched muscle. This fact, which suggests that the mechanoreceptors responsible for the myotatic reflexes lie in parallel with the laryngeal muscle fibres (and not in series with them), is in accordance with an observation made elsewhere[15]; namely, that slowly adapting discharges fired into the ipsilateral recurrent laryngeal nerve by stretching the thyro-arytenoid muscle are interrupted by active contraction of the muscle in response to its direct electrical stimulation.

That these low-threshold facilitatory myotatic reflexes normally make a continuous (though varying) contribution to the regulation of the tone of the laryngeal muscles is evidenced by the fact that motor unit activity in the left cricothyroid and thyro-arytenoid muscles was substantially reduced (in frequency and amplitude) when they were detached from the thyroid cartilage, in comparison with the homologous muscles on the right side—so long as these latter were not detached as well. Relevant in this respect are some previous reports[15,13] that sustained afferent discharges can be recorded from nerve fibres supplying the cricothyroid, thyro-arytenoid and posterior crico-arytenoid muscles *in situ*; and a further observation in the present experiments that graduated stretch applied to the left (detached) cricothyroid and thyro-arytenoid muscles could, if appropriately adjusted, restore their motor unit activity to a pattern identical with that in the normally attached homologous muscles on the right side.

Inhibitory myotatic reflexes. These reflexes, manifested by a sustained decrease in the amplitude and frequency of motor unit discharge in the stretched muscles, could be elicited also from the cricothyroid, thyro-arytenoid and sternothyroid muscles—but their production required greater degrees of stretch than the facilitatory reflexes. Thus, at the stage of anaesthesia at which 5 g stretch elicited clearly detectable facilitatory responses, at least 15 g of stretch was required to convert this into inhibition in the cricothyroid and thyro-arytenoid muscles, and at least 20 g in the case of the sternothyroid muscle. Further increases in the degree of stretch above these values produced greater degrees of inhibition in each of the muscles.

As with the facilitatory responses, the reflex inhibition was sustained throughout the period of applied stretch, and showed no signs of adaptation within the periods used in these experiments. Further, the inhibitory effect was equally sustained in both the tracheotomized and the non-tracheotomized animals; and in the latter there was more marked reduction of motor unit activity during the active phases of the respiratory cycle than during the resting phases. Unlike the facilitatory reflexes, then, the inhibitory myotatic reflexes are not aborted (but are augmented) during active contraction of the stretched muscle; and this might indicate that the mechanoreceptors responsible for the inhibitory effects are different from those evoking the facilitatory responses, lying in series with the muscles (and not in parallel) and having a higher threshold.

The transient on–off bursts of articular reflex origin were still evoked in the thyro-arytenoid and cricothyroid muscles by the application of weights in excess of 15 g to the thyro-arytenoid muscle, and were more marked than with lesser weights. In these circumstances, however, they occurred at the beginning and end of a period of sustained inhibition, instead of sustained facilitation.

Effects of changing anaesthesia. Alterations in the degree of barbiturate anaesthesia had a number of significant effects on the myotatic reflex responses in the laryngeal muscles.

Such reflexes were only elicitable in the early (that is, light) stages of anaesthesia, when the pulmonary ventilation rate of the animal was in excess of 600 ml./min and the corneal and swallowing reflexes were still present. A gradual increase in anaesthesia from this stage produced a rapid reduction in, and early abolition of, the facilitatory responses; and comparison of the stretch reflex responses in the intrinsic laryngeal muscles with those simultaneously elicited in the rectus femoris muscle showed that the laryngeal myotatic reflexes were totally abolished at stages of anaesthesia at which there was very little alteration in the myotatic reflexes in the limb muscle.

During gradually increasing anaesthesia, the myotatic reflexes in the laryngeal muscles began to diminish a little before the articular reflex responses occurring in the same muscles—and the former disappeared before the latter. This relation is the reverse of that obtaining with the myotatic and articular reflexes in limb muscles[20], during increasing anaesthesia. Both types of reflex were abolished in the larynx at quite moderate degrees of anaesthesia, however, and at a point far short of that

required for abolition of the myotatic reflex in the rectus femoris muscle. With gradual recovery from established anaesthesia, the reverse phenomenon occurred in that the myotatic reflexes in the limb recovered well before those in the larynx, and in the larynx the articular reflexes returned a little before, and recovered more quickly than, the myotatic reflexes.

It was also noted that a small increase in anaesthesia abolished the facilitatory responses in the laryngeal muscles before the inhibitory reflexes elicitable in the same muscles. Moreover, in such circumstances the threshold of the inhibitory reflex system was reduced, so that 10 g (or even 5 g) of applied stretch elicited an inhibitory response in a muscle in which the same degree of stretch only produced facilitatory responses at lighter anaesthesia.

Effects of sequential section of laryngeal nerves. The various effects of section of the different laryngeal nerves on the myotatic reflexes are still being investigated, but a few observations are pertinent here.

For example, division of all the laryngeal nerves on the right side of the larynx did not significantly alter the myotatic reflex responses in the muscle being stretched on the left side of the larynx. The same applies also to the articular reflex transients. In some experiments, division of the right external (or less often, the right recurrent) laryngeal nerve diminished the resting activity in the left cricothyroid muscle, but the myotatic and articular reflexes could still be elicited therein at the same threshold. In other experiments, division of the right recurrent laryngeal nerve low in the neck (between the tenth and twelfth tracheal rings) similarly reduced the resting activity in the left thyro-arytenoid muscle; but again the myotatic and articular reflexes remained readily elicitable in the muscle. Thus, while the contralateral external (and in some cases, the recurrent) laryngeal nerve may contribute some motor fibres to the cricothyroid muscle, and the contralateral recurrent nerve may contribute motor fibres to the thyro-arytenoid muscle, in neither case does a significant proportion of mechanoreceptor afferent fibres from these muscles appear to enter contralateral laryngeal nerves.

On the other hand, section of the left internal laryngeal nerve was found in a number of instances to reduce markedly (or even abolish) the facilitatory myotatic reflex responses in the ipsilateral thyro-arytenoid (and sometimes the ipsilateral cricothyroid) muscle without altering its resting activity. The rapidly adapting articular reflex responses in these muscles were always abolished in such circumstances, whether or not the sustained myotatic reflexes were affected. This is in accordance with our earlier observation[1,2,6] that most of the mechanoreceptor afferents from the crico-arytenoid joint enter the ipsilateral internal laryngeal nerve; but, in addition, it now seems that in some (but not all) animals a proportion of mechanoreceptor afferents from the intrinsic laryngeal muscles may enter the same nerve—as has been suggested elsewhere on the basis of degeneration studies[19].

In most animals, however, bilateral section of the internal laryngeal nerves had no effect on the myotatic reflexes in the thyro-arytenoid and cricothyroid muscles—although the articular reflexes from the crico-arytenoid joint were always abolished in these muscles by this procedure. It seems, therefore, that in most circumstances the myotatic reflex afferents from these two muscles do not traverse the internal laryngeal nerve.

Additional section of the external laryngeal nerves (which contain the bulk of the motor fibres innervating the cricothyroid muscles), or proximal section of the superior laryngeal nerves close to the ganglion nodosum, in the same animals usually abolished the myotatic reflex responses in the cricothyroid muscle without affecting those in the thyro-arytenoid muscle—although the last-mentioned responses were abolished in turn by further section of the left recurrent laryngeal nerve (which, of course, contains most of the motor fibres innervating the thyro-arytenoid muscle). It seems likely, then, that the myotatic reflex afferents from the thyro-arytenoid muscle usually (though not always exclusively) enter the ipsilateral recurrent laryngeal nerve, which also receives the mechanoreceptor afferent fibres from the ipsilateral cricothyroid joint[1,2,4–6]. This would accord with previous observations[15,13] that traction on the thyro-arytenoid (or posterior crico-arytenoid) muscles provokes slowly adapting discharges in afferent fibres in the recurrent laryngeal nerve that are interrupted during active contraction of the muscle.

The myotatic reflex afferent pathway from the cricothyroid muscle has not as yet been finally delineated in our experiments. In a few instances (*vid. sup.*) some afferent fibres from this muscle may enter the ipsilateral internal laryngeal nerve, but most do not. Whether they enter the external or the ipsilateral recurrent laryngeal nerve cannot yet be decided; but the overall impression from our findings to date is (surprisingly) in favour of the latter. This impression receives support from a report[13] that no afferent impulses could be detected in fibres of the external laryngeal nerve when the cricothyroid muscle was stretched.

We noted in some animals that section of the left internal laryngeal nerve might abolish the facilitatory myotatic reflex response in the ipsilateral thyro-arytenoid muscle (and occasionally in the cricothyroid muscle as well) without affecting the inhibitory reflexes in the same muscle. Furthermore, in some of these instances the threshold of the inhibitory reflex system was reduced (as happens also with a slight increase in anaesthesia), so that the application of 10 g (or even 5 g) of stretch after nerve section evoked an inhibitory response in place of the facilitatory response that was elicited beforehand with the same degree of stretch. This observation raises the possibility that afferent fibres mediating inhibitory myotatic reflex effects on the laryngeal muscles may follow, at least in some cases, a different peripheral centripetal pathway from those mediating facilitatory myotatic reflexes in the same muscles.

The following conclusions appear to be justified by the observations described in this article:

(1) Myotatic reflexes are elicitable (by passive stretch) in the intrinsic as well as in the extrinsic muscles of the larynx.

(2) The myotatic reflexes in the intrinsic laryngeal muscles are generated from low threshold, very slowly adapting, mechanoreceptors located within the muscles themselves, whence afferent fibres pass into the ipsilateral laryngeal nerve trunks—usually the recurrent nerve, but sometimes the internal laryngeal nerve.

(3) The laryngeal myotatic reflex systems are of two types—facilitatory and inhibitory, the former being of lower threshold than the latter. Whether this dichotomy is due to the operations of two types of mechanoreceptor ending of differing threshold in the laryngeal muscles, or whether it results from the differing central effects of low- and high-frequency discharges from the same receptor endings, is uncertain as yet; but the findings in the present investigation favour the former explanation.

(4) The myotatic reflexes in the larynx are distinct from the laryngeal articular reflexes in their functional characteristics—the former being tonic reflexes provoked from very slowly adapting mechanoreceptors, whereas the latter are phasic reflexes operated from rapidly adapting mechanoreceptors.

(5) The laryngeal myotatic reflex system seems to be polysynaptic and not monosynaptic, in view of its marked sensitivity to barbiturate narcosis, and resembles the laryngeal articular reflex system in this respect. The myotatic reflex system in the larynx thus differs markedly from the monosynaptic myotatic reflex system in the limb muscles.

We thank Sir Victor Negus for his continuing interest in these investigations, Prof. Ruth Bowden, of the

Anatomy Department, Royal Free Hospital School of Medicine, London, for the provision of histological facilities, and Mr. J. Kitau for technical assistance.

SENSITIZATION OF *Escherichia coli* TO RADIATION BY BROMOURACIL: EXCESSIVE POST-IRRADIATION BREAKDOWN OF DEOXYRIBONUCLEIC ACID WITHOUT CONCOMITANT SYNTHESIS

By Dr. SUSAN AOKI, Prof. RICHARD P. BOYCE and Prof. PAUL HOWARD-FLANDERS
Department of Radiology, Yale University School of Medicine, New Haven, Connecticut

E. COLI is known to excise thymine dimers from its DNA during incubation after ultra-violet irradiation. This excision of thymine dimers is accompanied by extensive breakdown of the DNA with the release of the products into the acid-soluble fraction of the cell and into the medium. Moreover, both thymine dimer excision and DNA breakdown occur in wild-type strains of *E. coli* that are able to repair their DNA, but both processes are greatly reduced in certain mutants, notably strains B_{s-1} and *K*-12 *uvr*$^-$, which are unable to repair ultra-violet-irradiated *T*1 phage[1–3].

In addition to excision and breakdown, exposure of *E. coli* to moderate doses of ultra-violet light causes a lag in DNA synthesis, following which there is a resumption of synthesis at nearly the normal rate. In mutants unable to excise thymine dimers, however, the return of DNA synthesis is less than 10 per cent of that in the wild type[4,5].

According to the recently developed theories on the mechanism of the enzymatic repair of DNA following exposure to ultra-violet light[1,2], repair occurs by the following processes: (1) enzymatic release or excision of defective bases such as thymine dimers, leaving gaps in one of the two polynucleotide chains; (2) enzymatic widening of these gaps by local single-strand degradation and release of nucleotides; (3) reconstruction of the strand by insertion of nucleotides using the intact opposite strand as a template (repair synthesis); (4) completion of the DNA chain by rejoining the phosphodiester linkage.

Bacterial cells which have 5-bromouracil (BU) in their DNA in place of thymine are very sensitive to ultra-violet light[6], to X-rays[7], to mitomycin *C*[8], and possibly to other deleterious agents. It has been suggested that the presence of BU in DNA sensitizes by inhibiting post-irradiation DNA repair[9,10]. According to the foregoing model, the inhibition of DNA repair by BU might be observed as the loss of ability to break down DNA or the failure to synthesize DNA after irradiation. In the present work, radioactive thymidine was used to follow the processes of DNA breakdown and synthesis in BU-substituted *E. coli* after exposure to ultra-violet light. The results indicate that irradiated DNA containing BU is extensively degraded and that DNA synthesis is inhibited; thus, the DNA is not effectively repaired.

The bacteria used were *E. coli K*-12 strain *AB*2416 *str*^{R}*thy*$^-$*uvr*$^+$ and *AB*2419 *Str*^{R}*thy*$^-$*uvrB*, which were derived from WS 110Y25 *thy*$^-$ obtained from Dr. Rivka Rudner. Cells were routinely grown in a salts–glucose medium enriched with 2·5 mg/ml. casamino acids and thymine. This will be referred to as *EM*9. Plating medium consisted of yeast extract–tryptone agar. For the determination of post-irradiation DNA breakdown, overnight cultures in *EM*9 containing 2·5 μc./ml. ^{14}C-thymine (25 μg/ml.) were diluted five times and grown about two generations in *EM*9 containing 5 μg/ml. ^{14}C-thymine alone, or 5 μg/ml. ^{14}C-thymine + 50 μg/ml. 5-bromouracil. In a similar experiment, using ^{3}H-bromodeoxyuridine and ^{14}C-thymidine (TDR), it was calculated that about 50 per cent of the thymine in the DNA was replaced by BU. Cells were collected and suspended in *M*9 for irradiation. For ultra-violet survival curves, or determination of post-irradiation DNA synthesis, cells were prepared as stated except that non-radioactive thymine was used.

Cell suspensions in *M*9 transparent to 2537-Å light were irradiated with a low-pressure mercury germicidal lamp. The dose-rate was 10 ergs/mm^2/sec. For survival curves, irradiated samples were diluted into cold broth, plated, and colonies counted after overnight incubation at 37° C.

To determine post-irradiation DNA breakdown, samples were taken from the suspension of labelled cells at intervals during incubation at 37° C. These were acidified with perchloric acid to 0·5 N, maintained at 4° C for 30 min, and centrifuged with heat-killed cells as carrier; the radioactivity in a small sample of the supernatant was counted in a liquid scintillation counter. To measure the total radioactivity of each sample, the pellets were dispersed in the same supernatants, the tubes were heated to 90° C for 40 min, centrifuged, and the radioactivity in the supernatants again counted. After digesting the pellet in hot acid in this manner, more than 98 per cent of the radioactivity was in the supernatant.

To measure DNA synthesis after irradiation, non-radioactive cells, previously grown in *EM*9 containing 5 μg/ml. thymidine or 1 μg/ml. thymidine + 5 μg/ml. 5-bromodeoxyuridine, were suspended in *EM*9 containing 2 μc./ml. ^{14}C-TDR (1·6 μg/ml.) and incubated at 37° C with aeration for 4 h. At 30-min intervals 0·1-ml. samples of the suspension were placed on Whatman 2·4 cm filter paper disks. Immediately 0·04 ml. of 1 per cent sodium hydroxide was added to each disk and allowed to dry. Iced 10 per cent trichloroacetic acid (TCA) was then added, and when dry, the disks were washed in cold 5 per cent TCA for 1 h, re-washed for 10 min, dried and counted in a liquid scintillation counter.

Fig. 1 shows the effects of 2537-Å light on the original parental *uvr*$^+$ strain and on a non-repairing (*uvr*$^-$) mutant of *E. coli* grown in the presence and absence of BU. It is seen that in the *uvr*$^+$ parental strain, cells grown in the presence of BU for 1·5 generations are much more sensitive to ultra-violet light. In contrast, growth in the presence of BU has no effect on the fraction of *uvr*$^-$ cells surviving

after ultra-violet irradiation. These results suggest that BU inhibits DNA repair in the *uvr*$^+$ parental strain, whereas in the *uvr*$^-$ mutant, which cannot excise thymine dimers, BU has no effect on the radiation sensitivity.

Fig. 2 shows that after exposure to ultra-violet light, *uvr*$^+$ cells containing ^{14}C-thymine labelled DNA release a large percentage of this radioactivity to the medium. Both the rate and extent of this release of radioactivity are markedly greater in cells labelled with BU. These results show that the presence of BU in place of thymine does not inhibit DNA breakdown after ultra-violet irradiation, but, on the contrary, enhances breakdown.

Since BU does not inhibit DNA repair by preventing breakdown, experiments were carried out to determine the ability of normal and BU-substituted cells to synthesize DNA after irradiation. Fig. 3 shows the rate at which ^{14}C-TDR is incorporated into normal and BU-labelled cells after ultra-violet irradiation. It is seen that cells containing BU show a striking loss of ability to synthesize DNA following ultra-violet irradiation.

The foregoing results support the conclusion that in *E. coli* only normal and not BU-containing DNA is effectively repaired. This inhibition is not due to any failure in the breakdown of DNA. As evidence for this, irradiated ^{14}C-thymine-labelled cells containing BU showed a greater release of radioactive label into the medium during incubation than did normal cells. In DNA which had 50 per cent thymine replaced by BU, the probability of forming an ultra-violet-induced thymine dimer should be decreased by a factor of 4. If only thymine dimer excision initiates DNA breakdown, then it could reasonably be expected that breakdown in BU-labelled cells would be inhibited. That such is not the case suggests that BU photoproducts may also be excised. Wacker[11] has shown that BU substituted for thymine in DNA is converted to uracil after ultra-violet irradiation. Smith[12] has isolated five debrominated products after ultra-violet irradiation from *E. coli* DNA containing BU. One product was uracil; the other products remain unidentified. Thus, uracil–uracil and uracil–thymine dimers might be among the photoproducts formed in BU-containing DNA. The latter has been identified in normal ultra-violet-irradiated DNA, arising from cytosine-thymine dimerization followed by deamination of the cytosine moiety[13]. This photoproduct is excised from DNA[2], and it is likely that uracil–uracil dimers would be similarly excised.

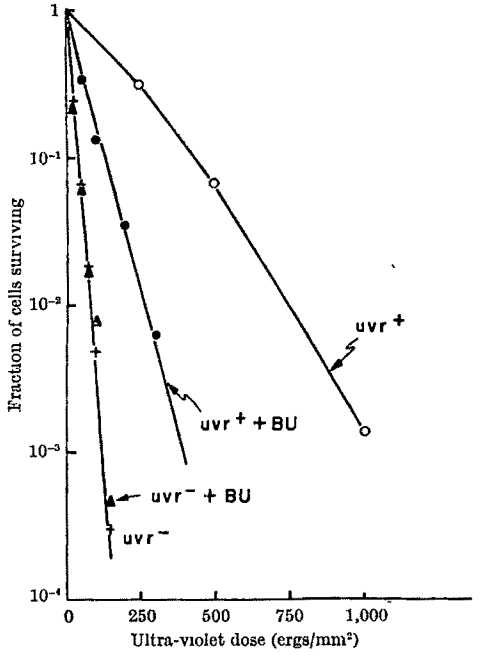

Fig. 1 Survival of colony-forming ability of *E. coli K*–12 *AB*2416 *uvr*$^+$ *thy*$^-$ and *AB*2419 *uvr*$^-$ *thy*$^-$ grown in normal and 5-bromouracil containing medium after ultra-violet irradiation. For details, see text

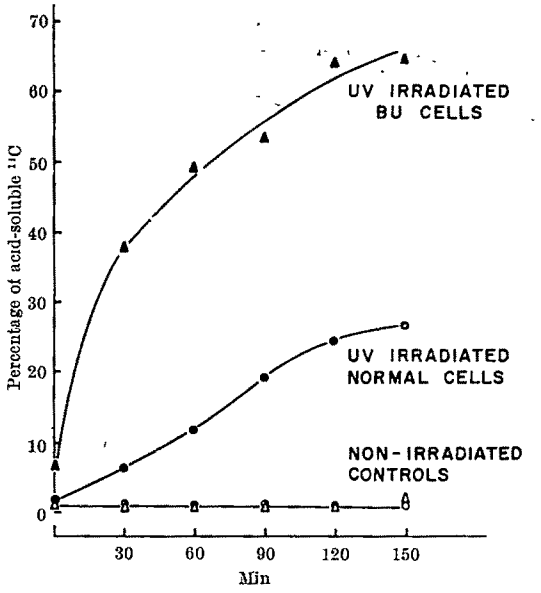

Fig. 2 Release of cold acid-soluble carbon-14 from ^{14}C-thymine labelled *E. coli K*–12 *AB*2416 *uvr*$^+$ *thy*$^-$ during incubation following ultra-violet irradiation. Washed cells grown in *EM*9, containing 5 μg/ml. ^{14}C-thymine (0·5 μc /ml.) or 5 μg/ml. ^{14}C-thymine plus 50 μg/ml. BU, were divided into two samples. One sample served as the unirradiated control, while the other was exposed to 1,000 ergs/mm^2 ultra-violet light. Both samples were transferred to *EM*9 containing 40 μg/ml. non-radioactive thymine and incubated at 37° C. At intervals the percentage of cold acid-soluble carbon-14 was determined as described in the text

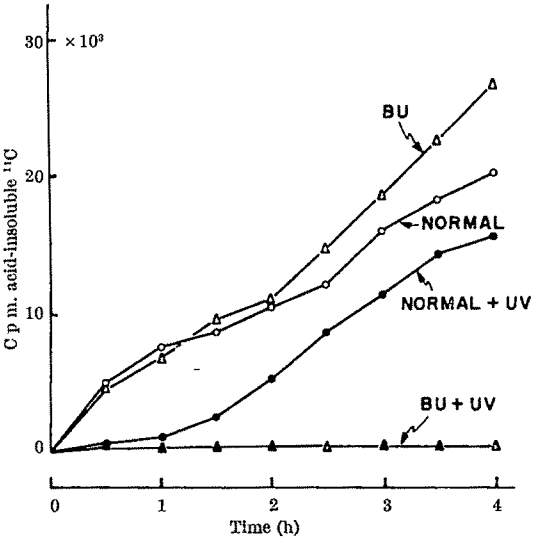

Fig 3. Incorporation of ^{14}C-thymidine into cold acid-precipitable material in normal and BU-containing *E. coli AB*2416 *uvr*$^+$ *thy*$^-$ after ultra-violet irradiation. Non-radioactive cells grown in the presence or absence of BUDR were transferred to *EM*9 containing 2 μc /ml ^{14}C-thymidine (1·6 μg/ml.) after no treatment or after exposure to 500 ergs/mm^2 ultra-violet light. The bacterial suspensions were adjusted to the same initial optical density and incubated at 37° C. At intervals cold acid-insoluble carbon-14 was determined per ml. of culture as described in the text

In comparison with normal cells, those with BU in their DNA exhibit a marked loss of ability to incorporate ^{14}C-TDR into cold acid-insoluble material after ultra-violet irradiation. There is negligible incorporation in the first 4 h after exposure to ultra-violet light, showing that neither DNA repair synthesis nor DNA replication occurs to any appreciable extent. In comparable experiments with X-rays in place of ultra-violet light, it was found that DNA breakdown in BU-containing cells was also greater than in the normal cells. After exposure to 10 krads, the ability to incorporate TDR into normal cells is decreased by only 10–20 per cent, while in BU-

containing cells, it is depressed by about 60 per cent[14]. This is in contrast to the present results obtained with ultra-violet light. Nevertheless, a similar mechanism of sensitization may be operative that involves a failure of DNA repair synthesis. The intermediate level of TDR incorporation after X-irradiation does not prove the contrary, as it may be due to DNA replication rather than repair synthesis; this point will need further work for elucidation.

In work with recombination defective mutants of *E. coli*[15], we have observed an interesting parallel in the ultra-violet-induced breakdown and synthesis in these strains and in normal cells containing BU as described here. This relationship will be pursued in future publications.

The loss of ability of BU-containing cells to synthesize DNA after ultra-violet irradiation may be closely related to the failure to repair DNA and to the abnormally high radiosensitivity. Indeed, the breakdown of 60 per cent of the DNA without concomitant DNA synthesis is indicative of the formation of two-strand breaks, which are presumably lethal. Since DNA repair synthesis follows post-irradiation breakdown in normal cells, it appears that the presence of BU primarily affects the change-over from exonuclease to repair polymerase at the sites of action in the DNA, perhaps by altering the relative affinities of the two enzymes so as to favour continued breakdown.

We thank Tessa Peruzzi and Eva Simson for assistance in this work, which was supported by grants *CA*-06519 and *AM-K*6-9397 from the U.S. Public Health Service.

PRODUCTION OF ADDITIONAL SITES OF DEOXYRIBONUCLEIC ACID BREAKDOWN IN BROMOURACIL CONTAINING *Escherichia coli* EXPOSED TO ULTRA-VIOLET LIGHT

By Prof. RICHARD P. BOYCE
Department of Radiology, Yale University School of Medicine, New Haven, Connecticut

THE substitution of 5-bromouracil (BU) in place of thymine in the DNA of bacteria renders them highly sensitive to the lethal effects of various deleterious agents, including ultra-violet light[1,2], X-irradiation[3] and mitomycin *C* (MC)[4]. Wild-type *Escherichia coli* (henceforth called *uvr*$^+$ bacteria) that are capable of repairing damaged DNA[5] undergo considerable breakdown of their DNA after exposure to ultra-violet light or to MC[6–8]. This breakdown is thought to be initiated from single-strand gaps left by the defect excision enzymes controlled by the *uvr* genes, and to be part of the repair process[7,9]. In *uvr*$^-$ mutants of *E. coli* that lack the ability to excise thymine dimers and which are unable to repair effectively DNA exposed to ultra-violet light or to MC, there is much less DNA breakdown[8]. The presence of BU in the DNA of *uvr*$^+$ bacteria markedly enhances DNA breakdown[10]. This article provides evidence which shows that BU enhances DNA breakdown to about the same extent in *uvr*$^-$ strains of *E. coli* as it does in *uvr*$^+$ strains. This result indicates that ultra-violet light causes additional sites of degradation in DNA containing BU, which do not depend on the action of the excision enzymes. This effect occurs in addition to that already reported by Aoki, Boyce and Howard-Flanders[10], for example, that DNA degradation is uncontrolled in BU-containing bacteria. We shall also show that MC-induced DNA breakdown is enhanced in BU-containing *uvr*$^+$ bacteria, but that breakdown does not occur in *uvr*$^-$ bacteria, even if they contain BU. This observation provides additional evidence that the presence of BU in DNA of bacteria favours the continued release of nucleotides once this release is initiated by the action of the *uvr* genes.

The bacteria used were the following strains of *E. coli* K-12: *AB*2416 *Str*^{R}*thy*$^-$*uvr*$^+$ and *AB*2419 *Str*^{R}*thy*$^-$*uvrB*, both derived from *WS*110*y*25; *AB*2497 *thy*$^-$*uvr*$^+$, derived from *AB*1157 *uvr*$^+$; *AB*2498 *thy*$^-$*uvrC*, derived from *AB*1884 *uvrC*; and, *AB*2500 *thy*$^-$*uvrA*, derived from *AB*1886 *uvrA*. The last-named three thymine-dependent strains were isolated using the procedure of Stacey and Simson[11]. In referring to *uvr*$^-$ mutants, *uvrA*, *uvrB*, and *uvrC* are used to denote the genetic loci in mutant strains unable to repair ultra-violet-irradiated *T*1 phage.

Cells containing BU and labelled with ^{14}C-thymine were prepared by growth for two generations in a salts–glucose medium containing 2·5 mg/ml. casamino acids, 5 μg/ml. ^{14}C-thymine plus 50 μg/ml. BU. 30–40 per cent of the cells grown in this manner were non-viable. When only ^{14}C-thymine labelled cells were desired, the BU was omitted. In some experiments, the tritiated nucleosides of thymine and BU were used.

Cells were washed three times in Luria broth, suspended in Luria broth, and grown for 20 min at 37° to reduce radioactive precursors in the acid-soluble fraction. The cells were again washed, suspended in phosphate buffer to give solutions that were more than 55 per cent transparent to 2537 Å light, and irradiated with a low-pressure mercury germicidal lamp.

Exposure to MC was in a salts–glucose medium at 37° for 30 min, after which the MC was removed by centrifugation.

To determine DNA breakdown after exposure to ultra-violet light or to MC, cells were incubated in complete medium containing 25 μg/ml. non-radioactive thymine, and the percentage of acid-soluble carbon-14 of cells and of the medium was determined as previously described[10]. DNA synthesis was determined by incorporation of ^{14}C-thymine into cold acid-precipitable material by the filter disk method previously described[10].

Fig. 1 shows that *uvr*$^+$ bacteria grown in the presence of ^{14}C-thymine and exposed to ultra-violet light release twice as much carbon-14 into acid-soluble material as do *uvrB* bacteria. In contrast, the release of acid-soluble

carbon-14 is enhanced to about the same maximal level in either strain if they are grown in the presence of BU. These results show that ultra-violet-induced DNA breakdown in bacteria containing BU in their DNA does not depend on functional *uvr* genes.

The kinetics of DNA breakdown for several doses of ultra-violet light in both *uvr*$^+$ and *uvrB* strains of *E. coli* grown in the presence of ^{3}H-thymidine and BUDR are shown in Fig. 2. DNA breakdown becomes almost independent of dose above 240 ergs/mm^2. For doses up to 1,000 ergs/mm^2, DNA breakdown in the *uvrB* mutant strain exceeds that in the *uvr*$^+$ strain by 20–30 per cent.

The incorporation of ^{14}C-thymine into acid-precipitable material by the same cells used in the experiment in Fig. 2 is shown in Fig. 3. Non-irradiated cells of both strains containing BUDR rapidly incorporate carbon-14 into acid-precipitable material. Incorporation of ^{14}C-thymine in either strain ceases after irradiation with 240 ergs/mm^2. Although this dose greatly inhibits DNA synthesis in *uvr*$^-$ bacteria containing thymine, it scarcely affects DNA synthesis in normal *uvr*$^+$ bacteria[12,13]. These results show that during the incubation period, in which 35–60 per cent of the DNA in BU-containing cells has been degraded, no DNA synthesis has occurred. Under these conditions, double-strand breaks must occur in the DNA. These would presumably be lethal to the bacterial cell.

Fig. 4 shows that the ultra-violet-induced release of acid-soluble radioactivity from ^{14}C-thymine labelled bacteria increases the longer the bacteria are grown in the presence of BU. This result suggests that the amount of release is proportional to the amount of BU incorporated into the DNA.

Wild-type *uvr*$^+$ bacteria containing BU are considerably more sensitive to the lethal effects of MC than are *uvr*$^-$ bacteria[4]. Fig. 5 shows that the presence of BU also enhances DNA degradation in *uvr*$^+$ cells after exposure to MC. However, in contrast with the results obtained with ultra-violet light, there is no breakdown of the DNA in *uvrB* cells exposed to MC, whether or not these cells contain BU. This shows that MC-induced DNA breakdown in *uvr*$^+$ bacteria is enhanced by the presence of BU only after breakdown has been initiated by the *uvr* genes. These results also suggest that MC does not produce single-strand breaks that can serve for the initiation of breakdown in DNA containing BU.

The ability of BU-containing cells to incorporate ^{14}C-thymine into acid-precipitable material is completely depressed by exposure of the cells to 5 μg/ml. MC, as shown in Fig. 6. Under these conditions normal bacteria still incorporate about 20 per cent of the amount of ^{14}C-thymine that the untreated cells incorporate.

Uvr$^-$ mutants map at three widely spaced loci called *uvrA*, *uvrB* and *uvrC*[13,14]. Experiments so far indicate that all three genes are required simultaneously in the excision of defective bases[13]. Table 1 shows the percentage release of acid-soluble radioactivity from thymine-dependent *uvrA*, *uvrB* and *uvrC* mutants grown in ^{14}C-thymine and BU, exposed to ultra-violet light or to MC, and incubated for 2 h. All three mutant strains undergo a large amount of DNA breakdown after ultra-violet irradiation, whereas treatment with MC produces much less breakdown. The results in Table 1 confirm that all three genes are concerned with the same function.

Normal *uvr*$^+$ bacteria are thought to repair damaged DNA through the following sequence of events: (1) excision of the defect in one strand of the twin polynucleo-

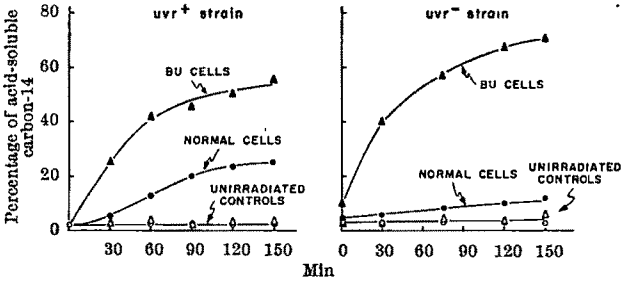

Fig. 1. Ultra-violet-induced release of cold acid-soluble radioactivity from normal and BU-containing *E. coli K*-12 *AB*2416 *uvr*$^+$*thy*$^-$ and *AB*2419 *uvrBthy*$^-$. Washed cells grown in ^{14}C-thymine with or without bromouracil, as described in the text, were untreated or exposed to 1,000 ergs/mm^2 2537 Å light. During incubation at 37° in complete medium containing 25 μg/ml. non-radioactive thymine per cent, cold acid-soluble carbon-14 was determined as previously described (ref. 10). Acid-soluble in all experiments includes the growth medium

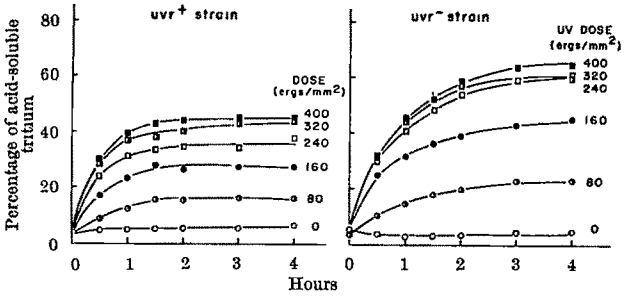

Fig 2. Release of cold acid-soluble radioactivity from BUDR-containing *E coli AB*2416 *uvr*$^+$*thy*$^-$ and *AB*2419 *uvrBthy*$^-$ for various doses of ultra-violet light. Cells were grown in medium containing 5 μg/ml. thymidine-methyl-^{3}H (^{3}H–TDR) alone or 5 μg/ml. ^{3}H-TDR plus 50 μg/ml. bromodeoxyuridine (BUDR) for two generations. Washed cells were exposed to the doses of ultra-violet light shown, incubated in complete medium containing 25 μg/ml. non-radioactive thymidine at 37°, and acid-soluble ^{3}H determined as previously described (ref. 10)

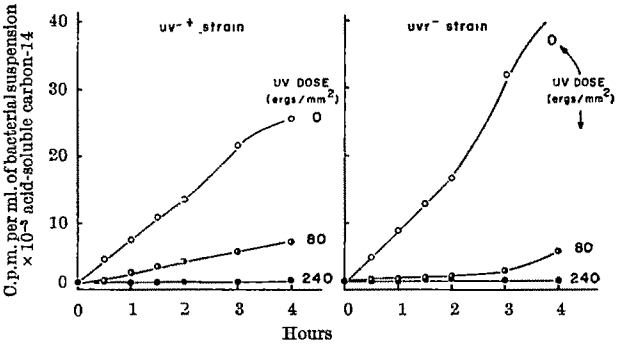

Fig. 3 Incorporation of ^{14}C-thymine into acid-precipitable material by BUDR-containing *E. coli K*-12 *uvr*$^+$*thy*$^-$ and *AB*2419 *uvrBthy*$^-$. The same cell suspensions used for the experiment in Fig. 2 were all adjusted to *O D* 0 1 after ultra-violet irradiation. Equal volumes were transferred to complete growth medium containing 2-2 μg/ml. ^{14}C-thymine and incubated at 37°. Cold acid-precipitable carbon-14 was determined by the filter disk method (ref. 10). The scintillation counter was adjusted to eliminate counts from tritium

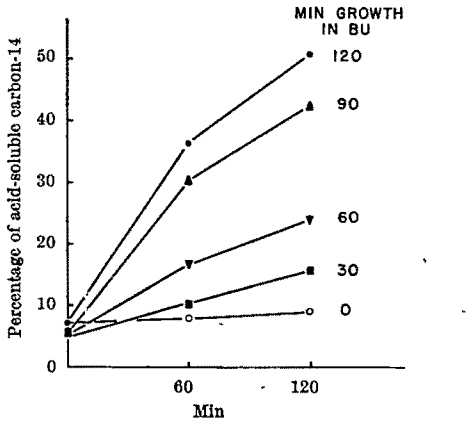

Fig. 4. Ultra-violet-induced release of cold acid-soluble carbon-14 from *E. coli* grown for various lengths of time in ^{14}C-thymine-BU medium. Overnight cultures were diluted five times into a glucose-salts-casamino acid medium containing 5 μg/ml. ^{14}C-thymine and 50 μg/ml. BU. At the times indicated, 2 ml. samples were filtered and washed on membrane filters, suspended in phosphate buffer to give a solution 80 per cent transparent to 2537 Å light, and ultra-violet irradiated with an effective dose of 1,000 ergs/mm^2. During post-irradiation incubation in complete medium containing 25 μg/ml. non-radioactive thymine, the percentage of cold acid-soluble carbon-14 was determined

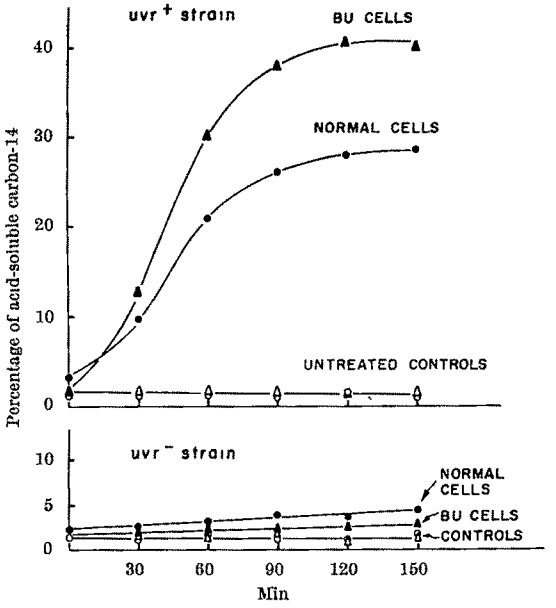

Fig. 5. Mitomycin *C*-induced release of cold acid-soluble radioactivity from normal and BU-containing *E. coli K*-12 *AB*2416 *uvr*$^+$*thy*$^-$ and *AB*2419 *uvrBthy*$^-$. Washed cells grown in ^{14}C-thymine with or without bromouracil as described in the text were exposed to 2·5 μg/ml MC for 30 min at 37° After removal of the MC by centrifugation the cells were incubated in complete medium containing 25 μg/ml. non-radioactive thymine, and the percentage of cold acid-soluble carbon-14 determined

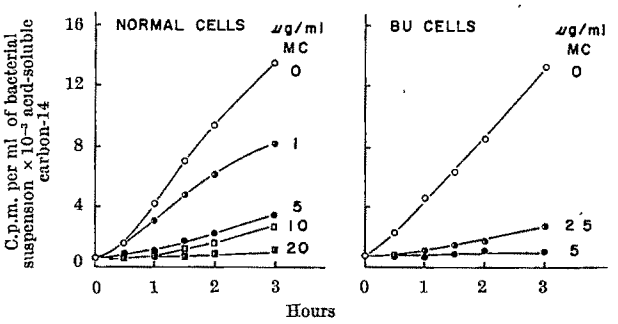

Fig. 6. Incorporation of ^{14}C-thymine into acid-precipitable material by BU-containing *E. coli K*-12 *AB*2416 *uvr*$^+$*thy*$^-$ after exposure to MC. Non-radioactive cells were grown in the presence or absence of BU and exposed to MC for 30 min at 37°. The MC was removed by centrifugation, and the cells suspended in complete medium to give the same optical density. To 1 ml. of cell suspension was added 2·2 μc /ml. ^{14}C-thymine, and cold acid-precipitable carbon-14 determined by the filter disk method (ref. 10)

tide; (2) exonucleolytic single-strand degradation, commencing at the site of excision; (3) reconstruction of the degraded strand by insertion of nucleotides into the degraded region (repair synthesis); (4) the formation of the phosphodiester link to the next section of intact polynucleotide. Implicit in this model of repair is the idea that DNA degradation gives way to DNA synthesis in some controlled manner[13]. Aoki *et al.*[10] suggested that this controlled switch-over from degradation to synthesis is altered by the presence of BU in DNA so as to favour continued degradation that ultimately produces double-strand breaks. The results of the present experiments confirm that BU enhances ultra-violet-induced breakdown

Table 1. Release of Acid-soluble Radioactivity from *E. coli* after Exposure to Ultra-violet Light or to Mitomycin C

Strain	% Acid-soluble carbon-14 after 2 h incubation following exposure to 1,000 ergs/mm² ultra-violet light	2·5 μg/ml MC
*AB*2497 *uvr*$^+$ *thy*$^-$	61	40
*AB*2500 *uvrA thy*$^-$	72	6
*AB*2419 *uvrB thy*$^-$	68	4
*AB*2498 *uvrC thy*$^-$	71	7

Bacterial cells were grown for two generations in a glucose-salts medium containing 2·5 μg/ml. casamino acids, and a 10 : 1 ratio (wt./wt.) of BU to ^{14}C-thymine. Washed cells were exposed to ultra-violet light or to MC, the MC removed by centrifugation, and incubated in complete medium containing 25 μg/ml non-radioactive thymine at 37° C.

in *uvr*$^+$ bacteria, but they also show that BU enhances to a similar degree DNA breakdown in *uvr*$^-$ bacteria. Thus, excessive breakdown in ultra-violet-irradiated bacteria containing BU is independent of the *uvr* genes, and suggests that major photo-defects exist in BU-containing bacteria after exposure to ultra-violet light, which are not removed by the excision enzymes. It is likely that these photo-defects are single-strand breaks[15], and that DNA degradation is initiated from such breaks, as also presumably occurs in normal bacteria exposed to X-rays[16].

Besides producing additional sites of DNA degradation in ultra-violet-irradiated *E. coli*, BU can also produce another effect. This is most clearly shown in the experiments with MC. Although MC induces enhanced DNA breakdown in BU-containing *uvr*$^+$ bacteria, it does not induce DNA breakdown in *uvr*$^-$ bacteria, even when they contain BU This provides direct evidence that BU can enhance MC-induced DNA breakdown only after it has already been initiated by the action of the *uvr* genes. This result supports the idea that BU alters the postulated switch-over from DNA degradation to synthesis so as to favour continued breakdown. This interpretation is strengthened by the observation that BU-containing bacteria exposed to ultra-violet light or to MC lose their ability to synthesize DNA during post-treatment incubation. In view of these results, the observed excessive DNA breakdown occurring in *E. coli* after ultra-violet irradiation can be interpreted in the following manner: the presence of BU in the DNA causes ultra-violet light to produce many single-strand breaks from which breakdown can proceed; and, independent of how breakdown is initiated—whether from the action of the *uvr* genes or whether from single-strand breaks—the presence of BU favours continued DNA breakdown by altering the normal switch-over from degradation to synthesis.

The alternative explanation, that in the *uvr*$^-$ mutants, the small amount of breakdown normally induced by ultra-violet is enhanced by the presence of BU, is rendered unlikely by the results obtained with MC. In those experiments, there was only about a third more breakdown caused by the presence of BU in *uvr*$^+$ bacteria. In contrast, ultra-violet irradiation produced a two- to three-fold increase in the DNA breakdown of BU-containing *uvr*$^+$ bacteria.

Another possible explanation for the observed extensive breakdown in *uvr*$^-$ bacteria after ultra-violet irradiation is that the presence of BU restores the action of the defective *uvr* genes, so that excision of ultra-violet photo-products can occur. This leads to uncontrolled breakdown as would be postulated in the *uvr*$^+$ strain. This explanation is not so attractive as that given here, because it is difficult to explain why the presence of BU in DNA would restore the action of the *uvr* genes for ultra-violet photo-products, but not for defects caused by MC.

The present results also show that BU-containing bacteria exposed to ultra-violet light or to MC are unable to synthesize DNA during a period in which they suffer extensive DNA breakdown. If this approaches 50 per cent of their DNA, it must result in double-strand breaks which presumably would be lethal to the cells, thus providing an adequate explanation for the increased sensitivity of BU-containing bacteria to irradiation, to MC, and possibly to other deleterious agents.

For doses of ultra-violet light of up to 1,000 ergs/mm² (the highest investigated), DNA breakdown in BU-containing *uvrB* bacteria was 20–30 per cent greater than in the *uvr*$^+$ strain. A possible explanation for this difference is that, since breakdown is proportional to the amount of BU in the DNA (Fig. 4), the *uvrB* strain incorporates more BU into its DNA than does the *uvr*$^+$ strain. Experiments using cells grown for two generations in the presence of ^{14}C-BU showed that there was 40 per cent more acid-precipitable carbon-14 in the *uvr*$^-$ strain per unit mass (as judged by optical density at 650 mμ) than in the *uvr*$^+$ strain. BU excision, controlled by the *uvr*

genes, might contribute to the cause for the relatively low amount of BU incorporated by the *uvr*$^+$ strain.

The enhancement of DNA degradation by the presence of BU in *uvr*$^+$ bacteria treated with MC may reflect the extent to which BU alters the normal switch-over from DNA degradation to synthesis in the repair process. Such an alteration could possibly arise because the presence of BU in DNA renders it an unsuitable template for repair synthesis, or because the exonuclease responsible for degradation has a high affinity for DNA containing BU. Another possibility is that BU degradation products interfere with the normal switch-over from degradation to repair synthesis. Experiments are at present being carried out to investigate these possibilities.

An interesting parallel to the experiments reported here is found in some *E. coli K*-12 mutants deficient in recombination, called '*Rec*$^-$' mutants[17]. Such mutants also manifest an apparent alteration in the controlled switch-over from ultra-violet-induced DNA breakdown to synthesis[18].

In summary, these investigations support the interpretation that sensitization of bacteria to radiation resulting from the incorporation of BU into their DNA is due to an enhancement of DNA breakdown and failure to synthesize DNA. The results also indicate that in *uvr*$^-$ mutants ultra-violet light causes strand breakage in DNA containing BU, whereas mitomycin *C* does not.

I thank Miss Tessa Peruzzi for her assistance, and Dr. Susan Aoki, Dr. P. Howard-Flanders and Dr. K. Stacey for suggestions and advice. This work was supported by U.S. Public Health Service grant, *CA*-06519.

IDENTIFICATION OF A COMPONENT OF A TRANSPORT 'CARRIER' SYSTEM: ISOLATION OF THE PERMEASE EXPRESSION OF THE *LAC* OPERON OF *Escherichia coli*

By Dr. ALAN R. KOLBER* and Dr. WILFRED D. STEIN
Department of Biological Chemistry, University of Manchester

OVERWHELMING evidence is available suggesting that certain components of cell membranes are involved in transporting across a lipid-protein barrier substances which are not ordinarily soluble in the hydrophobic structure of these membranes. It has been demonstrated by various kinetic approaches, in many different types of cells and tissues, that the transport of several classes of substances appears to be 'carrier-mediated'. Indeed, although these mobile reactive-sites (or 'carriers') have been inferred by that wealth of kinetic evidence, there remains as yet no single convincing demonstration of the characterization or identification of the elusive transport 'carrier', whether it be indigenous to the membrane, or part of the cytoplasm. It has been postulated, on the basis of certain evidence of a peripheral nature, that the system responsible for the transport of monosaccharides in the human erythrocyte is phospholipid in nature[1], or again, protein[2], but for this system the transport function has been shown to be confined to the plasma membrane[3]. The membrane-based sodium- and potassium-activated adenosine triphosphatase is clearly coupled with the transport of cations in a number of tissues[4]. Other evidence, of an even more indirect nature, suggests that the system for actively transporting β-galactosides into *Escherichia coli* has a protein, or enzymatic nature[5]. The genetic characterization of the *Lac* operon of this bacteria, which has been shown to contain genes for only three separate elements[6], and the fact that the manufacture of the products of the operon may be gratuitously induced by certain thio-substituted β-galactosides[7], have enabled us to separate and identify the gene-product of the operon mapped for 'permease' functions.

* Fellow of the U.S National Institutes of Health.

We have used the following mutant strains of *E. coli*, all of the *K*12 variety, which were kindly supplied by Prof. F. Jacob of the Institut Pasteur: 200*PS* (*FLac*$^+$), 200*P* (permease-less), and 2010 (galactosidase-less). Cultures of these mutants were re-isolated and sub-cultured on receipt, and were sub-cultured and maintained on nutrient agar slopes every 2 weeks thereafter. When prepared for experiment, the cells were cultivated in minimal salts broth[8], to which were added certain growth factors (vitamin B_1 and arginine) when required, and 0·2 per cent glycerol as a carbon source. The gratuitous inducer, β-thiomethylgalactopyranoside, was added (5×10^{-4} M) when required. The cultures were grown at 37° C for about 14 h, collected by centrifugation, washed with *tris*-succinate buffer (*p*H 7·4, 0·01 M) and the bacteria resuspended in the same buffer.

'Osmotically sensitive spheres' (OSS) were prepared according to Sistrom[9], and these were separated from the medium by high-speed centrifugation in the cold. The spheres were burst by the addition of a small volume of the dilute *tris* buffer (usually 15 ml. per g wet spheres). Bacterial membrane 'ghosts' were separated from the now very viscous supernatant (cell cytoplasm) by high-speed centrifugation in the cold. In order to separate the cytoplasmic proteins, aliquots of this viscous supernatant were applied to DEAE cellulose columns of varying dimensions. Best results were obtained when Whatman *P./DE* 100 *C.*2 DEAE cellulose (kindly supplied by Reeve Angel, Ltd.) was used. The columns were routinely eluted with a linear sodium chloride gradient (0–0·8 M) by the method of Bozk and Ling[10]. Effluent optical density (254 mμ) was continuously monitored by means of an L.K.B. (Sweden) 'Uvicord' recording system. Effluent

samples were assayed for protein (*O.D.* 280 mμ), β-galactosidase[11], thiogalactoside-transacetylase[12], and, in some cases, acid phosphatase[13].

The method used to separate the 'permease' gene product from the other cellular substituents of the crude bacterial extract involved double-isotopic labelling of the cellular proteins of a non-induced and induced culture with ^3H- and ^{14}C-labelled phenylalanine, one isotope to the former culture, the other to the latter. The uptake of ^{14}C-labelled phenylalanine by growing cultures of *E. coli*, the optimal conditions for such uptake, and subsequent separation of the proteins of a resulting cellular extract have already been reported[14]. The tracer amino-acid was supplemented with non-tracer phenylalanine to 10^{-4} M.

The cultures were grown under the aforementioned conditions, and the two mixed together before centrifugation. OSS and cell extract were prepared, and the cell extract applied to a DEAE cellulose column. 100 μl. of each effluent sample was applied to a paper disk (Whatman 3*M*) which was dried and placed in a vial containing a scintillation solution (dimethyl 1,4-*bis*-2-(5-phenyloxazolyl)-benzene (POPOP), polyphenol oxidase (PPO)). Counting was done on a Nuclear Enterprises, G.B., Ltd., liquid scintillation counter.

Electrophoresis of certain fractions of the DEAE cellulose chromatogram was carried out on a micro-scale using cellulose-acetate strips, and the protein fixed and stained with amido-schwartz dye (3 per cent trichloroacetic acid). Conventional procedures were followed[15]. Samples were prepared by concentrating pooled samples of the column effluent with powdered 'Carbowax' (a polyethylene glycol) in a dialysis bag.

For the case with the *FLac*$^+$ mutant, a large percentage of the protein manufacturing system of the cell is devoted to producing only those proteins coded for by the induced operon[16]; thus, areas of considerable ^{14}C-enrichment in a protein-radio-chromatograph of the crude bacterial extract should be readily apparent. Fig. 1 illustrates the results of such a chromatograph. For convenience in interpreting this and subsequent figures of like nature, one line (representing counts per unit time ^{14}C alone, or ^3H alone, of the effluents) was arbitrarily forced to coincide with the second line in an area of the chromatograph where the $^{14}C : {}^3H$ ratio was minimal, and hence where no ^{14}C-enrichment was to be expected. Thus, areas of ^{14}C-enrichment can be identified by the ^{14}C-line rising above the ^3H-line, and these areas are identified by the black, filled-in part of the figures (in Fig. 4, where the radioactive labels are reversed, the filled-in part indicates an area of tritium-enrichment). Results of analysis for enzymatic activity in corresponding samples appear as block diagrams beneath the lines representing the radioactivity.

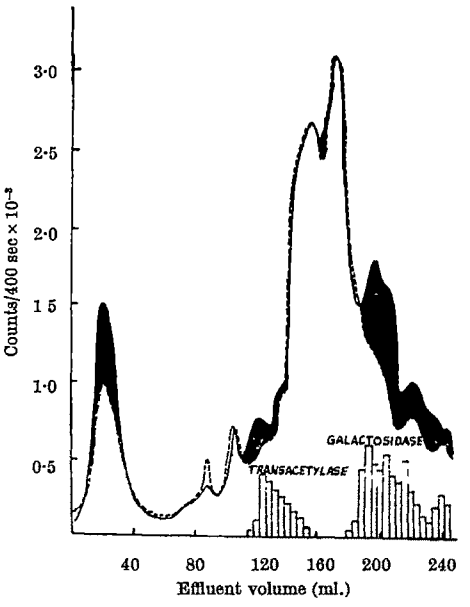

Fig 1. Effluent radioactivity and enzymatic activity of a cell extract of the *FLac*$^+$ (200*PS*) mutant of *E. coli* chromatographed on DEAE cellulose. ———, Carbon-14 content; — — — —, tritium content. Filled-in parts are carbon-14 enrichment (see text). Block diagrams represent indicated enzymatic activities drawn to an arbitrary scale. 7·5 ml. of the cell extract, from a total volume of 10 ml., was applied to the column. 2 ml fractions were collected, assayed, and counted. Tritium efficiency was 0·75 per cent, carbon-14 efficiency was 10 per cent. 0·40 mc. ^3H-phenylalanine was initially added to the non-induced culture; 0·01 mc. ^{14}C-phenylalanine was initially added to the induced culture

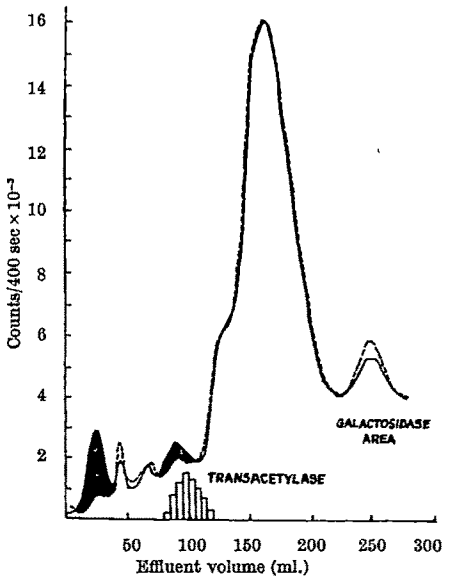

Fig. 2. Effluent radioactivity and enzymatic activity of a cell extract of the galactosidase-less (2010) mutant of *E. coli* chromatographed on DEAE cellulose. ———, Carbon-14 content; — — — —, tritium content. Filled-in parts are carbon-14 enrichment. Block diagrams represent indicated enzyme activities drawn to an arbitrary scale. *Galactosidase area* is that portion of the effluent volume which, if compared with the ultra-violet and radioactivity records of the two other mutant strains investigated, would ordinarily contain the galactosidase enzymatic activity. No such enzymatic activity was found here 7·5 ml. of the cell extract from a total of 9·5 ml. was applied to the column. 2·5 ml. eluate fractions were collected, assayed, and counted. Tritium efficiency was 0·5 per cent, carbon-14 efficiency was 10 per cent. 0·20 mc. ^3H-phenylalanine was initially added to the non-induced culture; 0·01 mc. ^{14}C-phenylalanine was initially added to the induced culture

Figs. 1, 2, and 3 illustrate the results of identical experiments conducted with each of the three mutant strains. Fig. 1 (*FLac*$^+$): there are three main areas of ^{14}C-enrichment present (the fourth, at the top of the centre peak, is created by one sample alone, has not been found in repeated experiments, and is considered by us to be probably a spurious record). Two of these areas are associated with corresponding areas of enzymatic activity. Clearly, the peak of ^{14}C-enrichment in the area of Fig. 1 associated with neither transacetylase nor β-galactosidase activity is not present in the comparable area of Fig. 3 (permease-less). But the two ^{14}C-enriched areas of Fig. 3 associated with β-galactosidase and *trans*acetylase activity both appear in areas of the chromatograph comparable with those of Fig. 1. Only the first area is missing. Fig. 2 illustrates the results for the mutant lacking galactosidase. Neither β-galactosidase enzymatic activity nor ^{14}C-enrichment appears on that part of the figure corresponding to the ^{14}C-enriched areas of Figs. 1 and 3. However, Fig. 2 does possess the ^{14}C-enriched area not associated with β-galactosidase or *trans*acetylase activity which appears in Fig. 1, but not in Fig. 3.

In order to obviate the possibility that the areas of enrichment were produced by fortuitous ^3H-quenching, the experiment was repeated with the labels reversed. Fig. 4 illustrates the results using the permease-less mutant. Again, no enrichment is noted in the 'permease'

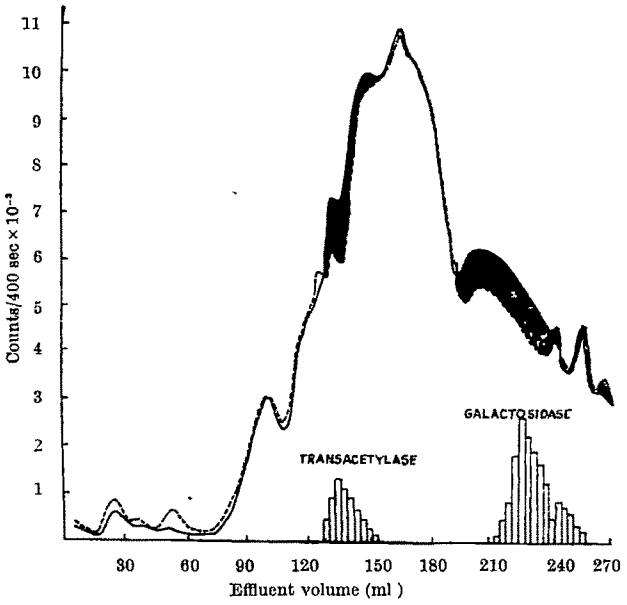

Fig. 3. Effluent radioactivity and enzymatic activity of a cell extract of the permease-less (200*P*) mutant of *E. coli* chromatographed on DEAE cellulose ———, Carbon-14 content; — — — —, tritium content. Filled-in parts are carbon-14 enrichment Block diagrams represent indicated enzyme activities drawn to an arbitrary scale. 3·5 ml. of the cell extract from a total volume of 5 0 ml. was applied to the column. Tritium efficiency was 0 5 per cent; carbon-14 efficiency was 10 per cent. 0 20 mc. ^{3}H-phenylalanine was initially added to the non-induced culture; 0 01 mc ^{14}C-phenylalanine was initially added to the induced culture

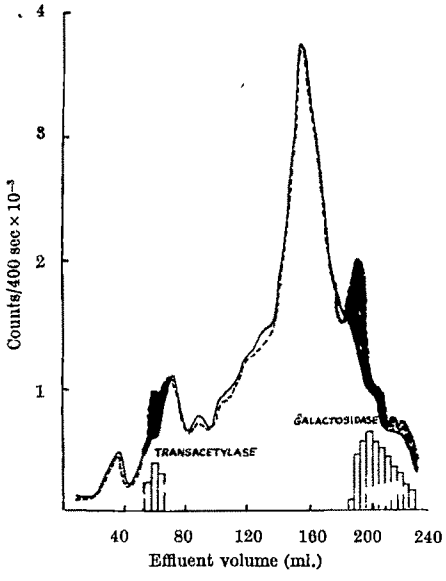

Fig. 4. Reversed-label (200*P*) experiment. Effluent radioactivity and enzymatic activity of a cell extract of the permease-less mutant of *E. coli* chromatographed on DEAE cellulose. ———, Carbon-14 content; — — — —, tritium content. The filled-in parts are tritium enrichment (see text) Block diagrams represent indicated enzyme activities drawn to an arbitrary scale. 7 5 ml of the cell extract from a total of 19 ml was applied to the column Tritium efficiency was 0·5 per cent, carbon-14 efficiency was 10 per cent. 0 02 mc ^{3}H-phenylalanine was added initially to the induced culture; 0 005 mc. carbon-14 was initially added to the non-induced culture

area, but the usual (now ^{3}H-) enrichment can be seen in each of the two areas identified with their respective enzymatic activities.

We now knew where the 'permease' area was to be found on the DEAE chromatograph, and we predicted, from the fact that the enrichment of the 'permease' peak was so much greater than that of the other two areas, that the material present in this region should be pure. With this in mind, we attempted to test the composition of effluent from this area. Fig. 5 illustrates the effluent tracing from a chromatograph of an induced culture of the *FLac*$^{+}$ mutant, while Fig. 6 is the effluent record from a chromatograph of a non-induced culture of the permease-less mutant. The figures are taken from the continuously monitored column effluent (*O.D.* 254 mμ). The absence, in Fig. 6, of the first major peak of Fig. 5 is clearly shown, and it is this area which, in the radiochromatographs, was observed to have enrichment designated as the 'permease' area.

The effluent samples from this 'permease' area of Fig. 5 were pooled, concentrated, and electrophoresed. Although there was little material present absorbing at 280 mμ, a single faint band took up stain. These investigations were

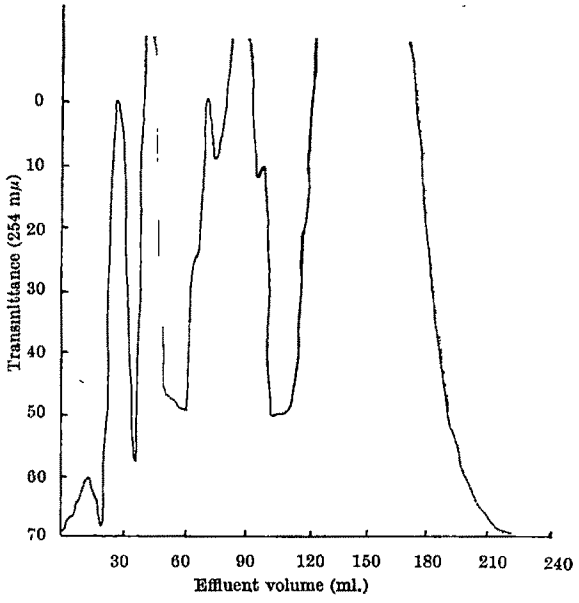

Fig. 5. Continuous tracing of the optical density (254 mμ) of the effluent from a DEAE cellulose column chromatograph of a cell extract from an induced culture of the *FLac*$^{+}$ (200*PS*) mutant of *E. coli*. 7·5 ml. of cell extract from a total volume of 17·5 ml. was applied to a DEAE cellulose column and eluted with 300 ml. of a linear gradient sodium chloride solution in 0 01 M *tris* buffer (see text)

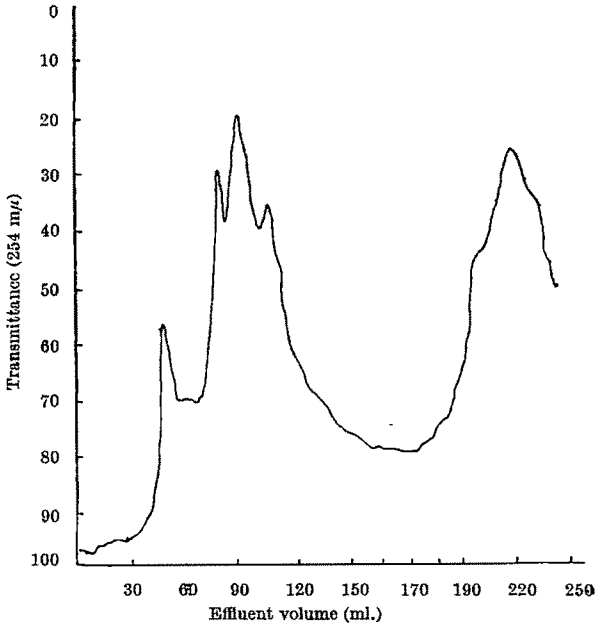

Fig 6. Continuous tracing of the optical density (254 mμ) of the effluent from a DEAE cellulose column chromatograph of a cell extract from a non-induced culture of the permease-less (200*P*) mutant of *E. coli* 7 5 ml of cell extract from a total volume of 17 ml. was applied to a DEAE cellulose column and eluted with 300 ml. of a linear gradient sodium chloride solution in 0 01 M *tris* buffer (see text)

of a preliminary nature; they are at present being pursued further.

The most direct conclusion which can be drawn from the results of the present investigations is that the enriched area of chromatographs 1 and 2, which has neither of the two enzymatic activities, is most likely to be the expression of the permease gene of *E. coli*. It would seem that the amount of permease is less than the amount of β-galactosidase formed, but somewhat greater than the amount of transacetylase formed. From the areas under the curves of Fig. 1, it can be computed that β-galactosidase is about 11 per cent of the total labelled soluble protein, the 'permease' is about 5 per cent, while the transacetylase is about 3 per cent. Nishi and Zabin[17] have shown that, in accordance with the theory of gene modulation, the amount of transacetylase formed is much less than the amount of β-galactosidase, about 0·13 per cent and 5·0 per cent, respectively, in bacteria grown at 37° C. Since the permease gene is mapped between the other two genes of the operon, it follows from this theory that the amount of permease formed should be somewhere between the amounts of the other two products, and this prediction is confirmed by our results. Our results suggest that, indeed, only three protein products are coded for by the three genes of the *Lac* operon, in accordance with the genetic predictions[18].

While we recognize the anomaly that the material present in our 'permease' area is presumably cytoplasmic, thorough extraction of the membrane fraction by vigorous methods[19] has failed to yield any enrichment. Thus, either the carrier may be extracted from the membrane by our technique into the supernatant, or what we have identified may only be some part of the complete system associated with the transport function. In such an event, it is possible that the carrier itself may not have been labelled by our technique. There is some indication that part of the cellular acid phosphatase activity may reside in this enriched area, suggesting a possible energy-supplying role for this component.

We are continuing our investigations, and at the same time are attempting to prepare large quantities of the material contained in this fraction of effluent. Moreover, we are seeking alternative procedures designed to label other classes of substances, particularly lipid and phospholipid, by a double-isotopic labelling technique.

INDUCTION OF TUMOUR IMMUNITY WITH TUMOUR CELLS TREATED WITH IODOACETATE

By Dr. CHARLES A. APFFEL, Dr. BARRY G. ARNASON
and
Dr. JOHN H. PETERS

Ira T. Nathanson Research Laboratories, Pondville Hospital, Walpole, Massachusetts; Department of Neurology, Massachusetts General Hospital, Boston; and Department of Microbiology, Harvard University School of Public Health, Boston

It is now clear that many lethal transplantable tumours in mice are to some degree antigenic for isogeneic or otherwise compatible hosts and that immunization of the host animal is in many cases possible with prevention or retardation of tumour growth on subsequent challenge using virulent tumour[1]. In the case of allogeneic tumours, a homograft-type reaction by the host against the foreign tissue is thought to be responsible. In the case of isogeneic tumours, 'tumour-specific antigens' to which the host has reacted are held responsible.

A major problem in the field, and in particular with isogeneic systems, has been to find an effective immunizing programme. Live, virulent tumour cells are not suitable as antigen since they may multiply and kill the host animal. Various methods have been used, therefore, to 'delethalize' tumour cells with preservation of their antigenicity. They have been processed by grinding, homogenizing, sonification, freeze-thawing, lyophilization and heat-killing, but all these techniques have led to destruction or severe loss of antigenicity[2]. One moderately effective immunizing technique has been the use, for immunization, of heavily irradiated tumour cells which, though viable, are unable to divide[3]. After an extensive course of immunization with cells thus treated, many mice will resist a lethal challenge with the corresponding tumour.

We have found that pretreatment of tumour cells with sulphydryl alkylating agents, particularly iodoacetate, suppresses their ability to induce tumours. This has occurred in all systems studied so far—allogeneic and isogeneic. The treated cells are viable; they respire at a subnormal rate. Mice treated with these cells develop intense immunity to the corresponding tumour, resisting challenge with doses of virulent tumour cells several times those which are uniformly lethal for control animals.

The initial observations were made using Ehrlich's ascites tumour in 3-month-old *A-jax* mice. In spite of its allogeneic nature, the Ehrlich's ascites carcinoma is fatal for all control mice, whatever the strain, so that a successful immunization is unmistakable. Fresh, unwashed Ehrlich's ascites tumour cells were incubated with 10^{-2}, 10^{-3}, 10^{-4} and 10^{-5} M sodium iodoacetate or simply in their own ascitic fluid for 1 h at 37° C and *p*H 7·4. After incubation, the tumour was diluted with physiological saline and groups of mice were injected intraperitoneally with the tumour cells. Each mouse was given $2·5 \times 10^6$ cells in 0·05 ml. of suspending medium. All mice injected with

untreated cells or with cells incubated with 10^{-5} M sodium iodoacetate developed ascites and died. Tumour did not develop in mice given cells incubated in 10^{-2}, 10^{-3}, or 10^{-4} M sodium iodoacetate although the cells excluded the supravital stains, safranin *O* and eosin *Y*.

Experimental mice were boosted twice at 14-day intervals with $2{\cdot}5 \times 10^6$ freshly prepared, treated cells. Fourteen days after the second booster, all experimental mice plus virgin controls were challenged with $2{\cdot}5 \times 10^6$ live, fresh Ehrlich's ascites carcinoma cells (several times the uniformly lethal dose). No animal pretreated with the 10^{-2}, 10^{-3}, or 10^{-4} M iodoacetate-inactivated cells developed a tumour during the observation period of 6 weeks. All control mice developed ascites and died within 2–4 weeks. Attempts to protect mice by immunization with tumour cell homogenates, following the immunization schedule given, were unsuccessful. All mice given the equivalent amount of 10^{-2} M sodium iodoacetate in saline died when later challenged. The results are summarized in Table 1.

Table 1. Effect of Sodium Iodoacetate on Tumour-producing and Immunogenic Capacity of Ehrlich's Ascites Tumour Cells

Immunizing material	Mortality after immunization	Mortality after challenge
Untreated tumour cells	20/20	—
Homogenized tumour cells	0/10	10/10
Iodoacetate-treated tumour cells 10^{-2} M	0/20	0/20
" " " " 10^{-3} M	0/20	0/20
" " " " 10^{-4} M	0/20	0/20
" " " " 10^{-5} M	10/10	—
Iodoacetate 10^{-2} M in saline	0/10	10/10
No cells given	—	20/20

It was found that immunity developed within a few days of the initial immunization. Groups of mice were immunized intraperitoneally with $2{\cdot}5 \times 10^6$ Ehrlich's ascites tumour cells pretreated with 10^{-2} M iodoacetate and challenged with $2{\cdot}5 \times 10^6$ virulent cells 2–21 days later. All mice challenged 2 or 3 days after immunization developed ascites tumours. Three of ten in each group afterwards overcame the ascites tumours and survived, but the rest died. Sixty-seven of seventy animals challenged between 4 and 13 days after immunization were protected, but only five of twenty in which challenge was delayed for 21 days resisted challenge. Peripheral blood total and differential white blood cell counts were done on mice given iodoacetate-treated cells intraperitoneally. At 3 days there was a profound drop in lymphocytes and polymorphonuclears reminiscent of that seen in a severe systemic delayed hypersensitivity reaction[4]. By 6 days, the polymorphonuclears had recovered to baseline levels and there was a considerable lymphocytosis.

Table 2 gives our results in an isogeneic system. The *MCT* sarcoma was methylcholanthrene-induced in our own (Pondville) sub-line of *C57BL* in 1960 and converted to its ascites form in 1964. Its growth is restricted to the strain of origin in which it is uniformly fatal. It will not grow in any other strain, not even in the closely related *C57BL/6*. Inactivation of ascitic *MCT* was complete at both concentrations used: immunization was effective but incomplete. Five of twenty-two mice succumbed eventually to the challenge with intraperitoneal tumour, but these five outlived all the controls.

Several other host–tumour combinations have been studied also and these are given in Table 2. The *EL4* tumour was completely inactivated and the immunity achieved in a co-isogeneic strain was as complete as it had been with Ehrlich's ascites tumour. With Krebs-2, using the same schedule, tumour inactivation was complete but immunization was partial. In later experiments, using a single immunizing injection with challenge after 7–10 days, a complete immunization was achieved. In this latter case, as well as with *MCT* tumour, incubation with 10^{-3} iodoacetate appeared to be more effective than incubation with 10^{-4} M.

We have found it possible to influence the growth of the subcutaneously implanted solid isogeneic *MCT* tumour described above by immunization with iodoacetate-treated cells of its ascitic form. Free *MCT* tumour cells in their ascites were incubated for 1 h in 10^{-3} or 10^{-4} M sodium iodoacetate. Individual mice were immunized with $2{\cdot}5 \times 10^6$ treated cells by intraperitoneal injection. Immunized mice plus a control group received subcutaneous solid *MCT* tumour by trochar the same day. Twenty days later they were killed. The individual solid tumours were dissected free and weighed. The results are given in Table 3. The retardation of tumour growth in both treated groups was highly significant although no treated animal was completely free of tumour.

In a second experiment, immunization was done with tumour cells prewashed in physiological saline before incubation with 10^{-4} M sodium iodoacetate. Again, the depression in mean tumour weight of treated mice, when compared to untreated controls at 28 days, was highly

Table 2. Effect of Sodium Iodoacetate on Tumour-producing and Immunogenic Capacity in Isogeneic, Co-isogeneic and Allogeneic Host-Tumour Systems in Mice

Tumour	Host strain	Relation of tumour to host	Immunizing material	Mortality after immunization	Mortality after challenge
MCT	*C57BL**	isogeneic	Sodium iodoacetate 10^{-3} M	0/11	1/11

significant and in three of twenty mice no tumour could be found. In two of ten mice immunized with prewashed iodoacetate-treated tumour cells 14 days after subcutaneous challenge with solid tumour, the established tumour had disappeared by 28 days. In several others, tumour growth was arrested.

Certain other reagents active on sulphydryl groups have been tested for their efficacy as inactivators. Iodoacetamide gave complete inactivation of Ehrlich's ascites tumour at 2×10^{-4} M but none at 1×10^{-4} M. With 10^{-3} and 2×10^{-4}, protection was complete; with 10^{-2}, nine of ten animals resisted challenge. *N*-Ethylmaleimide brought about an almost complete inactivation at 10^{-3} M and immunity was complete. *p*-Chloromercuribenzoate was ineffective. All animals inoculated with Ehrlich's ascites carcinoma pretreated with 10^{-3} M *p*-chloromercuribenzoate developed tumours.

We have found our alkylation technique to be a simple and effective means of inducing tumour immunity in situations where immunity has till now been difficult to produce. The mechanism by which iodoacetic acid and the other alkylating agents achieve their effect is uncertain. It would seem to be a direct effect on the tumour cell or on tumour cell antigens, rather than on the host, since iodoacetate alone failed to protect. It is well known that iodoacetate reacts primarily with sulphydryl groups; it may, in this way, inhibit enzymatic reactions essential for cell multiplication. Clearly, tumour growth was inhibited in these experiments; the mice were immunized with antigenically intact but harmless cells, and they responded to them. There is evidence that disulphide bonds are important in stabilizing the antigenic determinants of proteins[5]. Iodoacetic acid, by its action on sulphydryl groups, may stabilize tumour antigens as well.

The results with *MCT* and Krebs-2 tumours implicate some factor in addition to tumour inactivation in the immunity achieved. Treatment of either of these tumours with 10^{-4} M sodium iodoacetate led to less effective immunity despite complete tumour inactivation than did treatment with 10^{-3} M sodium iodoacetate, suggesting that iodoacetic acid affects tumour cell antigenicity directly. Why excess iodoacetic acid should interfere, even though minimally, with immunization to Ehrlich's ascites tumour cells is by no means clear. Conceivably, the excess iodoacetate might impede phagocytosis of antigen[6].

An alternative explanation would be that iodoacetate acts to thwart the production of enhancing antibodies, thus permitting a free field to the rejection mechanism. Preliminary data argue against such a view and indicate that enhancing antibody is produced normally in mice treated with lyophilized tumour exposed to iodoacetate.

Immunization with tumour cells treated with iodoacetate appears to be a powerful means of inducing tumour immunity. This is evidenced by the large proportion of animals that are made resistant to challenge, by the speed with which immunity is established, and by the ability of the treated cells to slow and in some cases reverse the course of an established solid tumour in an isogeneic system.

PASSIVE AND ACTIVE IMMUNITY TO FRIEND VIRUS DISEASE

By Prof. E. A. MIRAND, Dr. J. T. GRACE, jun., and R. F. BUFFETT

Roswell Park Memorial Institute, New York State Department of Health, and State University of New York at Buffalo, Buffalo, New York

Friend virus disease is characterized by proliferation of reticulum cell, erythroblastosis, hypervolaemic polycythaemia, leucocytosis, and hepatosplenomegaly[1–3]. When virus is injected into young or adult mice, the disease develops within a matter of a few days.

Earlier investigations showed that offspring from infected mothers developed the disease after a long latent period of more than 7 months[4]. This suggested to us that infected mothers are not only able to transmit virus to their offspring, but also to transmit some form of resistance to Friend virus disease. Several experiments were therefore carried out. Adult females of the *HA/ICR* and *DBA*/1 mouse strains were immunized at intervals after the onset of pregnancy (as determined by vaginal plug) with: (1) live Friend virus; (2) formalinized Friend virus vaccine; (3) heat-killed Friend virus. The offspring of these mice were in turn challenged with live virus at various intervals after birth. Offspring from non-infected females were injected with the same preparations and at the same time intervals.

Fig. 1 shows the results of challenge of offspring from Swiss mothers injected with live Friend virus on the second day of pregnancy. The 'percentage of protection' is the difference between the percentage of incidence of disease in offspring of non-infected mothers and the

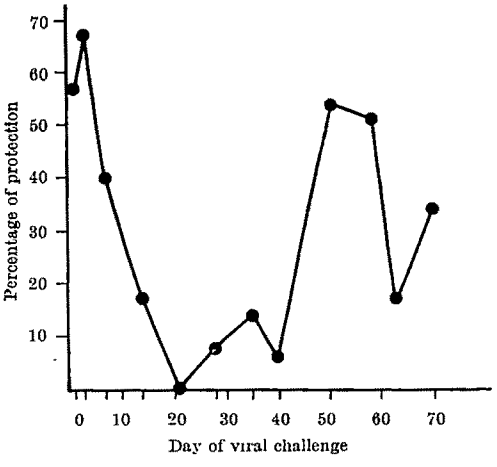

Fig. 1. Resistance of Friend virus disease in offspring of *HA/ICR* Swiss mother mice infected with Friend virus. Mothers were immunized intraperitoneally on second day of pregnancy with $10^{3\cdot1}$ $I.D._{50}$/0·1 ml. live Friend virus contained in a cell-free filtrate from spleens from Friend virus infected mice. Offspring were challenged subcutaneously, day 1, and thereafter intraperitoneally at intervals with $10^{2\cdot2}$ $I.D._{50}$/0·1 ml. live Friend virus. The same preparation was used throughout. Offspring from non-infected mothers were injected simultaneously

percentage of incidence in offspring of infected mothers. There is evidence of protection against Friend virus disease when offspring are challenged 1–15 days after birth. There is very little evidence of protection when mice are challenged 20–40 days after birth. However, there is renewal of protection when mice are injected 45 or more days after birth. We attribute the initial wave of protection to passive immunity, and the second wave to active immunity.

Fig. 2 shows the results of challenge of offspring from Swiss mothers that were injected with live Friend virus on the twelfth day of pregnancy. Offspring show very little resistance to the development of Friend virus disease when injected in the early period after birth. However, mice injected 20–28 days after birth are highly resistant. The delay in the initial passive immunity may be due to the lower antibody-level at delivery, since the mother was injected on the twelfth day of pregnancy. However, as the antibody rises in the mother, the offspring are protected by way of lactation. The second wave of active immunity occurs at approximately the same time as it did in the previous experiment.

Fig. 3 shows the results of challenge of offspring from *DBA*/1 mothers that were injected with live Friend virus on the twelfth day of pregnancy. The results are similar to those obtained from offspring of Swiss mice (Fig. 2), but the degree of protection as the result of passive immunity is much less in *DBA*/1 mice. This may be due to the fact that *DBA*/1 mothers received one log dose less virus than the Swiss mothers. However, protection due to active immunity, although delayed by about 20 days, is just as effective as in Swiss mice.

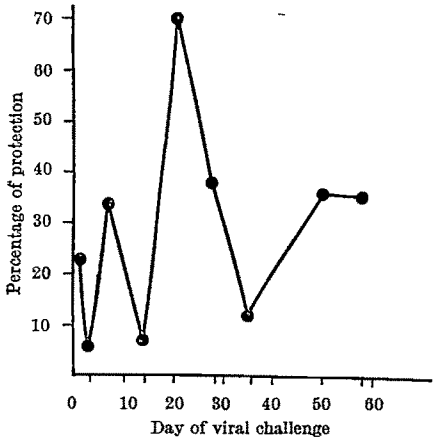

Fig. 2. Resistance of Friend virus disease in offspring of *HA/ICR* Swiss mother mice infected with Friend virus. Mothers were immunized intraperitoneally on twelfth day of pregnancy with $10^{3\cdot4}$ $I.D._{50}$/0·1 ml. live Friend virus. Offspring were challenged subcutaneously, day 1, and thereafter intraperitoneally at intervals with $10^{2\cdot9}$ $I.D._{50}$/0·1 ml live Friend virus

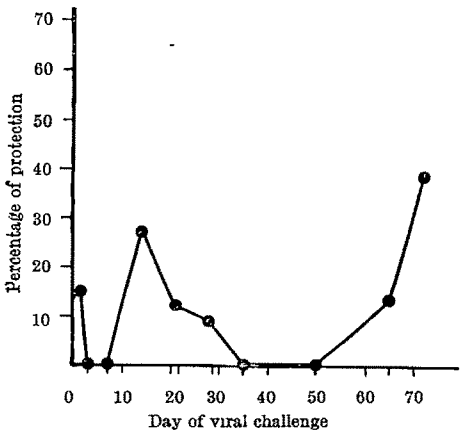

Fig. 3 Resistance of Friend virus disease in offspring of *DBA*/1 mother mice infected with Friend virus. Mothers were immunized intraperitoneally on twelfth day of pregnancy with $10^{2\cdot4}$ $I.D._{50}$/0·1 ml. live Friend virus. Offspring were challenged subcutaneously, day 1, and thereafter intraperitoneally at intervals with $10^{2\cdot5}$ $I.D._{50}$/0·1 ml. live Friend virus

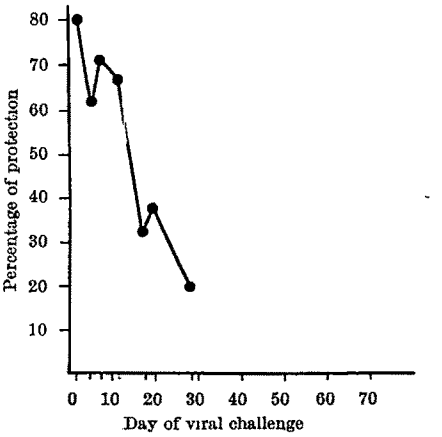

Fig. 4. Resistance of Friend virus disease in offspring of mother mice receiving formalinized Friend virus vaccine. Swiss mother mice were injected three times, on the third, seventh and tenth days of pregnancy, with a formalinized vaccine prepared with $10^{3\cdot8}$ $I.D._{50}$/0·1 ml. live Friend virus. Enough formalin was added to cell-free filtrate from spleens to give a final concentration of 1 : 500. The mixture was kept at 4° C and shaken manually daily for 30 days. Offspring were challenged subcutaneously, day 1, and thereafter intraperitoneally at intervals with $10^{2\cdot9}$ $I.D._{50}$/0·1 ml. live Friend virus

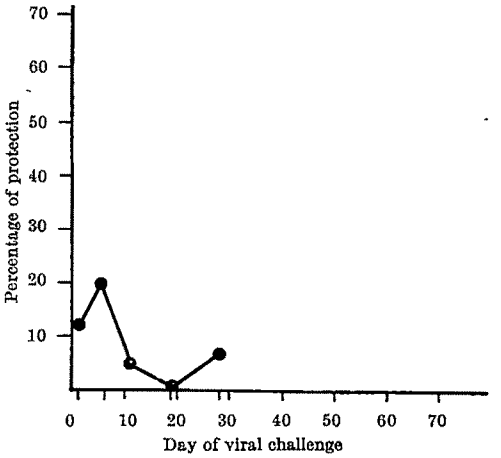

Fig 5. Resistance of Friend virus disease in offspring of mother mice receiving heat-killed Friend virus vaccine. Swiss mother mice were injected three times, on the third, seventh and tenth days of pregnancy, with a heat-killed vaccine prepared with $10^{3\cdot1}$ $I.D._{50}$/0·1 ml. live Friend virus. Cell-free filtrate was inactivated in a water bath for 2 h at 100° C. Offspring were challenged subcutaneously, day 1, and thereafter intraperitoneally at intervals with $10^{2\cdot8}$ $I.D._{50}$/0·1 ml. live Friend virus

In order to demonstrate that we are dealing with passive immunity, Swiss females were immunized with formalinized Friend virus vaccine. Mothers were injected three times, on the third, seventh and tenth days of pregnancy, and offspring were challenged at intervals after birth with live virus.

Fig. 4 shows the results. Protection against the development of Friend virus disease by passive immunity was essentially the same as when mothers were injected with live virus on the second day of pregnancy. The experiment is still in progress. However, protection should not occur in the later time intervals after birth, since live virus was not present in the formalinized vaccine.

Fig. 5 shows the results with heat-killed vaccine. Mothers were injected three times, on the third, seventh and tenth days of pregnancy, and offspring were challenged with live virus at intervals after birth. Very little protection was obtained against development of the disease during the period of passive immunity. This suggests that the heat-killed virus was an inadequate antigen and did not elicit a good immune response in the mothers.

Table 1. Resistance to Development of Friend Virus Disease

Week of challenge*	% protection	Offspring from infected mothers† Unprotected animals Average mortality (days)	Average spleen wt. (g)	Offspring from non-infected mothers Average mortality (days)	Average spleen wt. (g)

Range		(38–65)	(2·3–3 5)	(35–44)	(2·7–3 8)

* Data pooled at weekly intervals.
† Mothers injected on second day of pregnancy.

Table 1 summarizes the data from offspring of Swiss mothers injected with live virus on the second day of pregnancy. Data are pooled at weekly intervals. As seen in the previous figures, the early period of passive immunity and the later period of active immunity are clearly seen in the column "% protection". The next column shows the average age of death of those animals that were not protected; spleen weights are shown in the third column. The average age at death and spleen weights of infected offspring from non-infected mothers are shown in the last two columns. Offspring from this group showed virtually no resistance to the disease. It should be noted that, although spleen weights are relatively uniform throughout, there is a longer interval to death of offspring from infected mothers during periods of passive and active immunity than of offspring from non-infected mothers. Although these animals were not fully protected against development of the disease, they must have had some degree of resistance to progression of the disease.

The data from all experiments are presented in Table 2. Data are pooled at weekly intervals. In all instances, protection due to passive immunity was evident. The best protection was obtained with formalinized vaccine. In all instances, passive immunity is short-lived and disappears at 3–5 weeks after birth, or at about the time the animals are weaned. As shown in the previous figures, there is a period when protection is essentially absent, following the period of passive immunity. This is followed later by protection which is presumably due to the development of active immunity.

Table 2. Percentage of Protection against Challenge with Friend Virus

Pre-treatment of pregnant mothers	Week of challenge* 1	2	3	4	5	6	7	8	9	10

a, Swiss (3, 7, 10)†	16	5	0	7						

* Data pooled at weekly intervals.
† Day of pregnancy

A young mammal derives its immunity passively from the mother either before, after, or both before and after birth[5]. It is interesting to note in the results presented here that transmission of passive immunity continues for about 28 days after birth in the mouse, and stops abruptly. Our data seem to fit with those of others[6], indicating that the transmission of passive immunity in the mouse is most effective during the period of suckling. This is unlike the situation in the guinea-pig, rabbit and man (Table 3). However, passively acquired antibodies are transmitted postnatally, not prenatally, in the ox, goat, sheep, pig and horse, but for a period of only 36 h; in the dog, mouse and rat the time interval is longer.

Table 3. Time of Transmission of Passive Immunity in Mammals

Species	Transmission of passive immunity Prenatal	Postnatal
Ox, goat, sheep	0	+ + + (36 h)
Pig	0	+ + + (36 h)
Horse	0	+ + + (36 h)
Dog	+	+ + (10 days)
Mouse	+	+ + (16–28 days)
Rat	+	+ + (20 days)
Guinea-pig	+ + +	0
Rabbit	+ + +	0
Man	+ + +	0

In all instances, passive immunity is short-lived. The mechanism (or mechanisms) which causes the cessation of this capacity of the organism to respond is not well understood.

POSSIBLE EFFECT OF MITOTIC RECOMBINATION ON GENE CONVERSION AND NEGATIVE INTERFERENCE

By M. J. HARTLEY and Dr. W. J. WHITTINGTON
School of Agriculture, University of Nottingham, Sutton Bonington, Loughborough

In recent years it has become recognized from work with a variety of ascomycetes that segregation of gene loci may occur in ratios differing from 1 : 1. Extensive tetrad analysis[1–5] has established the occurrence of all the possible ratios—namely 5 : 3, 6 : 2, 7 : 1 and 8 : 0. The explanations usually put forward to account for these ratios, which imply gene conversion, have been based on copy-choice[6,7], although the 7 : 1 and 8 : 0 ratios are difficult to account for in this way.

We here examine the possibility that these ratios can be explained by the occurrence of a mitotic recombination immediately before meiosis. The model proposed assumes that mitotic recombination occurs by breakage and reunion after reduplication of DNA in a diploid nucleus and, furthermore, that each chromatid contains at least four DNA strands. Recombination of two strands between two chromatids differing in a gene could account for the 6 : 2 ratio (Fig. 1). The remaining 5 : 3, 7 : 1, and 8 : 0 ratios would result from recombination of one, three and all four strands respectively. If the initial break were between one double helix of each chromatid, then separation of the chromatids could result in further breakage of the same strand or perhaps—less frequently—of the sister strands (Fig. 2). An event of the former kind would lead to gene conversion for a limited number of closely positioned loci, while the remainder of the genes would segregate normally. This is in fact the result usually observed.

The exchange postulated here has an interesting effect on negative interference in that, provided that the breaks span a marker, a quarter of the strands in a nucleus affec-

ted by the mitotic exchange will enter meiosis in the double recombinant state. Clearly the effect of such previous recombination on the frequency of the double recombinant class will be considerably diluted by meiosis in unaffected cells. Consideration of the expected frequency of double crossing-over with different dilution factors shows that previous mitotic division could have a marked effect on coincidence, particularly where the genes are close together, and could give values greater than 100 (Tables 1 and 2). It therefore appears possible that previous mitotic exchange could both determine gene conversion and contribute to negative interference.

The proposed model is open to many obvious criticisms. The four-stranded chromatid was proposed because four is the smallest number which can account for the 5 : 3 and 7 : 1 ratios. Yet recent evidence[8] has shown that ascospores may be heterozygous for their DNA which suggests that more than four strands of DNA may be present in each chromatid. In higher organisms there is,

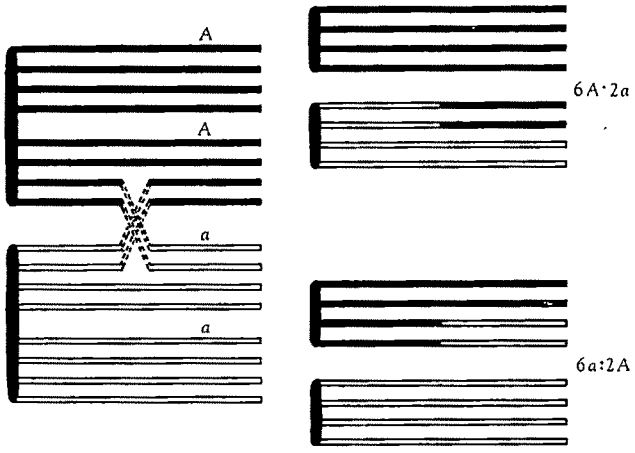

Fig. 1. Derivation of 6 , 2 ratios for alleles *A*, *a*, from the breakage of only two strands of a four-stranded chromatid. The figure shows only the daughter cells from the appropriate segregation of the chromatids at the mitotic division

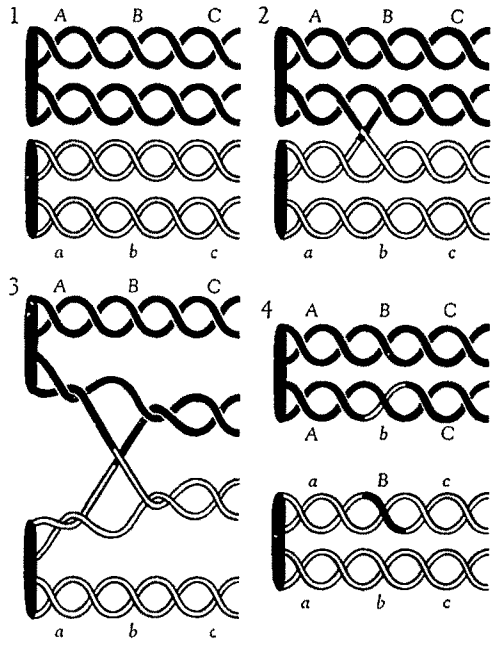

Fig 2 The derivation of double recombinant strands at a mitotic division. Each chromosome is composed of two chromatids, each of two double helices of DNA (1 chromatid = 4 DNA strands) Each helix, which should also have spiral form, is represented by a single black or white line 1, The initial state. 2, Showing the point of breakage of two strands of DNA in each chromatid. 3, The separation of the chromatids causes break-backs for each chromatid 4, The double-recombinant *AbC* and *aBc*

indeed, doubt as to the number of DNA strands in each chromatid. Electron micrographs have indicated that chromatids in the fern *Todea barbara* may have four strands[9], with the two helices formed into a major spiral. Alternatively they may be multi-stranded[10]. Experimental evidence from sea-urchin eggs[11] shows that the zygote nucleus is capable of dividing directly into four nuclei after only one replication of DNA, thus indicating that its chromatids consist of at least four strands. It is also well established that sub-chromatid breaks may occur[12]. There is clearly no certain evidence that fungal chromatids are four-stranded, but it is reasonable to assume that the level of organization of the DNA may lie between that of the bacterial cell and that of higher organisms.

The majority of ascomycetes do not have a true diploid mitosis, fusion of unlike haploid nuclei only occurring immediately before meiosis. It is possible that fusion may occur earlier, though infrequently, or that the diploid nucleus in the ascus initial may occasionally divide again before meiosis. Yet another possibility exists, for it has been shown that in the basidiomycete *Schizophyllum commune* recombination between haploid nuclei apparently occurs[13]. Evidence has also been presented for haploid recombination in *Neurospora crassa*[14], where it was found to occur between non-homologous chromosomes and would seem to be related to their organization during mitosis. There is, in fact, a growing body of evidence which is difficult to reconcile with the generally accepted processes of recombination[15]. Thus it seems possible to assume that mitotic recombination of the type assumed in our model may occur between overlapping homologous chromosomes, particularly if division of the nuclei is synchronized. This can happen only after the disappearance of a nuclear membrane at a time when DNA synthesis has already occurred.

The frequency of aberrant ratios is low and ranges from approximately 0·1–0·38 per cent in *Neurospora*[4], 0·042 per cent in *Aspergillus*[16], and 0·01–0·07 per cent in *Sordaria*[5] to 0·002 per cent in *Ascobolus*[17]. In yeast, on the other hand, which may have a true diploid phase, the apparent frequency of conversion is higher[2] although other explanations have been put forward for the abnormal spore ratios[18].

The model proposed here assumed that meiosis follows immediately after mitotic recombination. If meiosis is delayed by further mitotic divisions without recombination, then potential 6 : 2 ratios may become 8 : 0 ratios, while potential 5 : 3 ratios may become first 6 : 2 and then 8 : 0 segregations. The majority of aberrant ratios appear to be 6 : 2 or 5 : 3 events, with 8 : 0 less frequent and 7 : 1 extremely rare. It would, therefore, appear that if mitotic recombination is related to gene conversion, it must occur soon before meiosis.

Mitotic recombination within diploid nuclei is generally regarded as rare. If the results given here for the effect of mitotic recombination on conversion and negative interference are to be valid, then the ratio of affected to unaffected meioses should accord with previous evidence. The frequency of exchange has been estimated to be approximately 1 in 500 mitoses[19], but this is based on the exchange of whole chromatids. It may be that the part chromatid exchanges would be more difficult to recognize genetically, although there is no reason to assume that they would be more frequent than whole chromatid exchanges. It is probable that in Tables 1 and 2 the dilution ratio of one affected to ten unaffected is too low, and that the ratio 1 to 100 is more likely. It will be noted that the greater dilution still gives coincidence values of 3·54 and 26·0 for genes 0·1 and 0·01 units apart respectively. On the other hand, in *Fusarium oxysporum* a frequency as high as one recombination in forty nuclei has been found[20]. On this basis a coincidence value of about 100 might be obtained with genes 0·01 units apart, and this result would be similar to those already reported[21,22]. It will be noted,

Table 1. Coincidence Values, Percentage of Expected Aberrant Ratios and Variation in Percentage of Parental, Single and Double Recombinant Classes for Genes 1 Unit Apart, based on a Two-strand Exchange Model

Genotype	Frequency from unaffected meioses	Frequency from meioses affected by previous mitotic exchange	1 Mitosis : 10 meioses dilution factor 1 . 1,000	1 Mitosis : 100 meioses dilution factor 1 : 10,000
Parental	98 01	73·51	97 985	98 0075
Recombinant region 1	0·99	0·99	0 990	0·9900
Recombinant region 2	0·99	0·99	0·990	0 9900
Recombinant region 1+2	0 01	24·51	0·035	0·0125
	Coefficient of coincidence		3·333	1·244
	Aberrant ratios		0·05	0·005

Note: The dilution factor is calculated on the assumption that a mitotic recombination will occur with (1/10)th or (1/100)th of the frequency expected for a meiotic recombination per unit length.

Table 2. Effect of Gene Distance on Coincidence Values and Percentage of Aberrant Ratios with Ratios of 1 Mitosis per 10 or 100 Meioses, based on a Two-strand Exchange Model

Dilution factor calculated as in Table 1

Distance between genes		1 Mitosis : 10 meioses	1 Mitosis : 100 meioses
10 units	Dilution factor	1 : 100	1 : 1,000
	Coincidence	1·2	1·02
	Aberrant ratios	0·5	0·05
1 unit	Dilution factor	1 : 1,000	1 : 10,000
	Coincidence	3·333	1·244
	Aberrant ratios	0·05	0·005
0·1 unit	Dilution factor	1 : 10,000	1 : 100,000
	Coincidence	25·15	3·54
	Aberrant ratios	0 005	0·0005
0 01 unit	Dilution factor	1 : 100,000	1 : 1,000,000
	Coincidence	250·0	26·0
	Aberrant ratios	0·0005	0·00005

occurs before the first locus, the result of such an event in association with normal meioses, is some increase in negative interference. In fact, the more the cells are affected in this way, the more similar the situation becomes to that envisaged by Pritchard[24]. Thus some cells show meiotic recombination while others fail to do so because they are homozygous and not because pairing is ineffective. Positive interference is brought about when single mitotic recombination occurs between the sites, since these events change a proportion of the parental strands into one or other of the single recombinant classes. Finally, the less likely occurrence of multiple exchange would lead to positive interference for recombination before *A*, *B* and *A*, *C* and negative interference for the remaining possibilities. The negative interference values would not be high, for although the double recombination frequency rises, so also does the frequency of single recombinants. The results contrast with those obtained for part-chromatid exchange, where the double recombinant group increases without alteration of the single recombinant values.

It appears that other workers have not considered the possibility that mitotic recombination could affect meiotic segregation. This has probably been due not only to an almost exclusive interest in meiosis but also to the belief that mitotic recombination is too rare to be of interest. It is apparent from the foregoing discussion that mitotic recombination does offer explanations alternative to those

Table 3. The Effect of Prior Mitotic Recombination occurring in Different Regions of a Three-gene Model on the Frequency of the Parental (*a*), the Single Recombinant (*b*, *c*) and the Double Recombinant Class (*d*) obtained at Subsequent Meiosis

Genetic classes obtained at meiosis		Site before which prior mitotic recombination occurs						
	None	*A*	*B*	*C*	*AB*	*AC*	*BC*	*ABC*
Parental	*a*	$a+\frac{1}{2}(b+c+d)$	$\frac{1}{2}(a+b)+\frac{1}{2}(c+d)$	$\frac{1}{2}(a+c)$	$\frac{1}{2}(a+b)+\frac{1}{2}(c+d)$	$\frac{1}{2}(a+c)+\frac{1}{2}(b+d)$	$\frac{1}{2}(a+b+c+d)$	$\frac{1}{2}(a+b+c+d)$
Recombinant in region 1	*b*	$\frac{1}{2}b$	,,	$\frac{1}{2}(b+d)$	,,	$\frac{1}{2}(b+d)$	,,	,,
Recombinant in region 2	*c*	$\frac{1}{2}c$	$\frac{1}{2}(c+d)$	$\frac{1}{2}(a+c)$	$\frac{1}{2}(c+d)$	$\frac{1}{2}(a+c)+\frac{1}{2}(b+d)$	,,	,,
Recombinant in region 1+2	*d*	$\frac{1}{2}d$	,,	$\frac{1}{2}(b+d)$	,,	$\frac{1}{2}(b+d)$	,,	,,

however, that the frequency of aberrant ratios found for genes 0·01 unit apart at this dilution is at the lower limit of the distribution given above.

Kitani *et al.*[5] found a high frequency of exchange between the markers on either side of conversion event which was, however, more evident in 5 : 3 rather than in 6 : 2 asci. They believed that this disparity was difficult to reconcile with previously postulated explanations of conversion. In the model under discussion the mitotic recombinations leading eventually to 5 : 3 and 6 : 2 ratios produce at meiosis either a 'heterozygous' chromatid with two dissimilar DNA duplexes, or a 'heterozygous' chromosome with two dissimilar chromatids. It is possible that the high frequency of recombination associated with gene conversion is due to instability between the strands, the effect being greatest where the chromatids are of mixed genetic constitution. This may, therefore, represent a return to Pontecorvo's suggestion[23] that a high frequency of recombination may be associated with heterozygosity even though, in this instance, the heterozygosity is within the chromosomes rather than between them.

The foregoing discussion has been concerned largely with part chromatid exchange. Pontecorvo[19] was concerned with the exchange of whole chromatids rendering genes distal to the point of recombination homozygous in half the affected cells. In order to examine the possible effect of recombination before and between three genes on the coefficient of coincidence, an estimate was made of the results from such events (Table 3). In making the estimates it was assumed that recombination could initially affect any chromatid at random and that the separation of the chromatids after mitotic recombination was also at random. The results of the subsequent meiosis are presented in Table 3. Where mitotic recombination already proposed for gene-conversion and negative interference. The model is essentially simpler than many and it offers a real advantage over mechanisms which involve copy-choice. For, while the proposed model involves only one process of recombination, copy-choice also requires breakage and reunion to explain tetra-type asci.

The hypothesis could be supported by further evidence and in particular from estimates of conversion in higher organisms where the longer diploid phase of growth should allow greater evidence of the effect of part or whole chromatid exchanges.

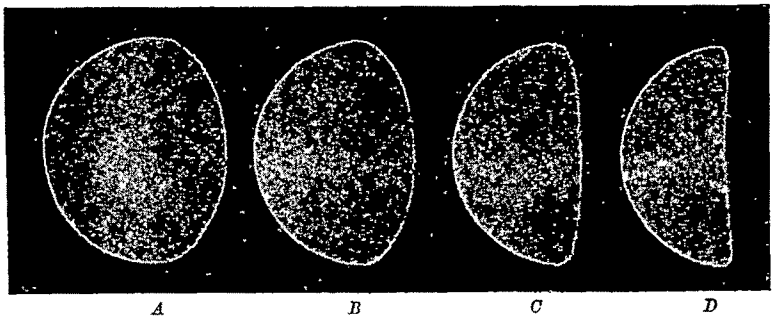
LETTERS TO THE EDITOR

ASTRONOMY

Possible Luminescence Effects on Mercury

A GROWING body of evidence leads to the conclusion that luminescence effects occur on the lunar surface. Large intensity fluctuations on the Moon have been observed photographically by Kopal and Rackham[1], spectroscopically by Spinrad[2], and photometrically and polarimetrically by Gehrels *et al.*[3]. If the luminescence phenomena are induced by the solar wind (see Nash[4]), we might do well to look to other bodies in the solar system, which are similarly unprotected by an atmosphere, for evidence of luminescence.



Fluctuations in the intensity of portions of the surface of the planet Mercury were recorded by Antoniadi[5–7], who regarded the apparent obscuration of dark areas as the result of variable cloud cover. From his extensive observations with the 33-in. Meudon refractor, Antoniadi concluded that the density and extent of the 'clouds' varied with the changing distance of Mercury from the Sun, probably reaching maximum at perihelion and minimum after aphelion.

The newly derived rotation period of Mercury reported by Pettengill and Dyce[8] casts some doubt on the long-term changes reported by Antoniadi because his conclusions were based on the assumed 88-day period. Antoniadi[5] also noted, however, that changes occur on Mercury in a few tens of hours, and these cannot be simply explained in terms of the shorter rotation period. Other observers have also reported short-period changes on Mercury[9].

In the interval 1958–64, I made an extensive series of observations of Mercury with telescopes up to 82 in. in aperture. Visual studies of Mercury are difficult owing to the proximity of the planet to the Sun, but my observations generally confirm that variations in the intensity of certain of Mercury's markings can occur in a matter of several hours or days.

Fig. 1 shows four drawings of Mercury made in a nine-day period in 1963. Drawing *A* was made with a 36-in. reflector and the remainder with a 12-in. reflector, all in fairly good seeing conditions. Between the first and last drawings in Fig. 1, a darkening at the south cusp is apparent. Later drawings made as the crescent waned show the south cusp darkening further until it was the darkest region on the planet. The apparent change in the interval of three days between *A* and *B* may be related in part to the higher resolving power of the 36-in. telescope used for *A*.

The great similarities between the Moon and Mercury that have been pointed out by many investigators and the probable luminescence phenomena on the Moon may make it possible to interpret changes on Mercury as the effects of luminescence of the surface materials.

GEOPHYSICS

Night-time Electron Temperatures in the Upper *F* Region

SATELLITE observations indicate that night-time electron temperatures in the upper *F* region are larger than the neutral gas temperatures. Willmore[1] estimates that an energy input $Q/n_e = 1{\cdot}5 \times 10^{-6}$ eV sec^{-1} is required at 650 km to maintain the temperature difference, and he suggests that bombardment by electrons of kilovolt energies might provide a suitable source. This communication shows that his suggestion is consistent with an upper limit on the precipitated flux of fast electrons set by optical observations[2].

The rate of electron heating due to bombardment by fast electrons is:

$$Q = p\frac{\mathrm{d}E}{\mathrm{d}x} v n_{ef} \text{ eV cm}^{-3} \text{ sec}^{-1} \qquad (1)$$

where $\mathrm{d}E/\mathrm{d}x$ is the energy loss in eV per cm path, p is the fraction of this loss converted to kinetic energy of the ambient electrons, and v is the velocity and n_{ef} the number density of the fast electrons. The energy loss due to collisions of fast electrons, of energy E eV, with ambient electrons is[3]:

$$\left(\frac{\mathrm{d}E}{\mathrm{d}x}\right)_e = \frac{2 \times 10^{-12}}{E} n_e \text{ eV cm}^{-1} \text{ for } E > 3 \text{ eV}$$

Using (1) and (2) and taking $p = 1$, $Q/n_e = 1{\cdot}5 \times 10^{-6}$ and $E = 10^3$, Willmore[1] obtained:

$$v n_{ef} = 7 \times 10^9 \text{ cm}^2 \text{ sec}^{-1}.$$

The precipitated flux of fast electrons is:

$$J = \frac{1{\cdot}6 \times 10^{-12}}{\varphi} E v n_{ef} \text{ ergs cm}^{-2} \text{ sec}^{-1} \qquad (3)$$

where the factor $1{\cdot}6 \times 10^{-12}$ converts eV to ergs and where φ is equal to 1 if the fast electrons are incident vertically and all effects of the magnetic field are neglected. With $\varphi = 1$, $E = 10^3$ and $v n_{ef} = 7 \times 10^9$ we obtain $J = 10$ ergs cm^{-2} sec^{-1}. This cannot be correct, since[2] the optical observations of N_2^+ emissions indicate that J cannot exceed some 10^{-2} ergs cm^{-2} sec^{-1}. We consider two effects which greatly reduce the value of J which is consistent with the suggested mechanism of ionospheric heating.

The energy loss due to excitation and ionization of neutral atoms of number density n_a is:

$$\left(\frac{dE}{dx}\right)_a = \frac{2 \times 10^{-12} \ln (E/80)}{E} n_a \text{ eV cm}^{-1} \text{ for } E > 500 \text{ eV} \quad (4)$$

We are interested in altitudes for which, at night, $n_a \sim 100\, n_e$. Comparing (2) and (4), we see that the fast electrons lose most of their energy in collisions with neutral atoms. About a quarter of this loss is accounted for by the kinetic energy of secondary electrons produced in ionizing collisions. The secondary electrons have $E \simeq 10$ eV. Dalgarno, McElroy and Moffett[4] estimate that:

$$\left(\frac{dE}{dx}\right)_a \simeq 10^{-16} n_a \text{ eV cm}^{-1} \text{ for } E \sim 10 \text{ eV} \quad (5)$$

Comparing (2) and (5), we see that the secondary electrons lose most of their energy in collisions with the ambient electrons. We may therefore use (4) in (1) with $p = 1/4$. This gives $vn_{ef} \simeq 10^8$ cm^{-2} sec^{-1}.

The second effect we consider is the reduction in J due to magnetic field trapping of fast electrons. Assuming that kilovolt electrons are injected at equatorial latitudes with isotropic pitch angle distributions, the factor φ in (3) has been calculated on solving a Fokker–Planck type of diffusion equation, allowing for scattering and energy degradation processes. This calculation, which will be described in detail elsewhere[5], shows φ to be of order 100. We therefore conclude that the electron heating can be explained with precipitated fluxes J as small as 10^{-3} ergs cm^{-2} sec^{-1} and hence that the discrepancy with the optical observations is removed.

It is of interest to consider the ionization which would be produced by fast electrons. Since each ionization provides the ambient electrons with about 10 eV of kinetic energy, the electron production rate is $q = (Q/10)$ electrons cm^{-3} sec^{-1}. Thus, with $(Q/n_e) = 1{\cdot}5 \times 10^{-5}$ eV sec^{-1} and $n_e = 10^4$ cm^{-3} we obtain $q = 0{\cdot}015$. It may be noted that the value of Q determined from observations of electron temperatures sets a limit on q which is more stringent than the limit set by optical observations.

Argon Retentivity of Nephelines

Nepheline[1] is the most characteristic feldspathoidal mineral in alkaline rocks and occurs in volcanic, plutonic and metasomatic rocks. In particular, these nepheline-bearing rocks occur fairly widely in the Canadian Shield.

The idealized formula of this framework silicate is $Na_3K(Al_4Si_4O_{16})$, which corresponds to a potassium concentration of 6·69 weight per cent. Reported values[1] range from 3 per cent to 10 2 per cent, rendering nepheline potentially suitable for dating by the potassium–argon method. An investigation has therefore been begun to test this possibility by examining the retentivity of nephelines for argon. Some of the preliminary findings are presented here.

All the samples have been collected from the Grenville province of the Canadian Shield, where muscovites, amphiboles and biotites are well known[2,3] to yield potassium–argon ages in the range 800–1,200 m.y. Samples of at least this age are necessary, since some minerals, for example some feldspars[4,5] and glauconite[6,7], while apparently reliable in the 0–100 m.y. range, are definitely unreliable when found in older rocks. The retentivity has been tested by comparing the potassium–argon age obtained on the nepheline with that given by a co-existing biotite or amphibole, these two minerals being generally accepted as exhibiting high argon retentivity[8,9].

Table 1 shows the initial findings of this programme. The immediate result which is clear from the data is that nepheline appears to retain argon extremely well over periods of at least 10^9 years, since in no instance is the nepheline age less than that of the associated mineral. The nepheline and biotite from Princess Quarry agree exactly in age. In the four other examples reported, the nepheline actually yields a slightly higher age than the corresponding index mineral. The age of the Goulding-Keene nepheline exceeds the average biotite age by 4·6 per cent, and the replicate analyses performed would seem to indicate that this small difference is real. In the three remaining samples, the nepheline unambiguously indicates a higher age. Thus, for samples from Gill Quarry and Blue Mountain, the nepheline ages are greater than those of the biotites by 16 per cent and 12 per cent, respectively. The potassium–argon age of the nepheline from the Bigwood Township nepheline syenite exceeds that of the amphibole (extremely fresh hastingsite) by 18 per cent.

λ_ε equals $0\ 584 \times 10^{-10}$ yr.$^{-1}$. λ_β equals $4\ 72 \times 10^{-10}$ yr^{-1}. ^{40}K equals 0 0119 per cent potassium, atomic.

It could be argued that the data indicate that potassium–argon ages determined with nephelines are anomalously high. For example, argon may have been trapped by the framework structure as a result of metamorphism of the nepheline syenites during which nepheline reacts with feldspar[10]. However, this is not considered likely at present since in no case does the nepheline age exceed the typical values found by potassium–argon dating in the Grenville. Evidence is accumulating that uranium–lead and whole-rock rubidium–strontium ages are systematically higher than potassium–argon mineral ages in complex metamorphic terrains[11,12]. It is of more than passing interest, therefore, that the nepheline ages come closer to concordance with those measured by other means. However, at the present time, it is not at all clear whether the divergences between the results of different methods are the results of errors in the various decay constants[13], the differing responses of different mineral types and decay systems to later metamorphism, or whether the measured ages represent the different times of closure of the systems during uplift and cooling[14,15]. The high argon retentivity of nephelines having been established, however, it does seem that a systematic potassium–argon investigation of nephelines will shed some light on this fundamental problem in geochronology.

In this work, potassium concentrations have been determined by flame photometry, using lithium as an internal standard and sodium as a buffer. Radiogenic argon-40 analyses were performed on an '*MS*10' mass

spectrometer after dilution with argon-38. Inter-laboratory comparisons have shown that any single age obtained is accurate to ± 5 per cent[16].

We thank W. J. Kenyon for skilful assistance with the argon extractions. This investigation is supported by the National Research Council of Canada. One of us (R. M. M.) thanks the Canadian Commonwealth Scholarship Committee for support during the project.

METALLURGY

T-phase Precipitation induced by the Addition of Silver to an Aluminium–Copper–Magnesium Alloy

RECENTLY attention has been directed to the effects of small amounts (approximately 0·1 atomic per cent) of silver on the structure and properties of certain age-hardening aluminium alloys, since the changes that occur are thought to have both fundamental and practical significance[1–7]. As part of this work, a detailed investigation is being made of silver additions to a wide range of aluminium–copper–magnesium alloys and some interesting results have been obtained for aluminium–2·5 per cent copper–1·5 per cent magnesium (contents expressed in weight percentages). As reported previously[5], the addition of 0·5 per cent silver to this alloy both accelerates the rate of ageing and causes increased hardening in the medium temperature range (120°–240° C) (Fig. 1). Reasons for these changes have now been sought using X-ray diffraction and transmission electron microscopy to investigate alloys which were solution-treated at 500° C, cold-water quenched, and aged at 200° C in a salt bath. Results are shown in Figs. 1 and 2.

The ternary alloy age hardens in two stages. The first stage occurs very rapidly and is due to the formation of a uniform dispersion of G.P.B. zones throughout the matrix. The second rise in hardness is associated with the growth of clusters of the precipitate *S* (possibly *S′*), which is lath-shaped and nucleated on dislocation lines generated during or immediately following quenching. The appearance of *S* at peak hardness is shown in Fig. 2*a*, and other evidence indicated that G.P.B. zones were also present. Softening occurs by the growth of *S* and the disappearance of G.P.B. zones. These results are in accord with earlier observations made on similar alloys by Silcock[8] and Wilson and Forsyth[9].

In the silver-containing alloy, two-stage ageing was again evident, but the morphology and dispersion of the precipitate particles were completely changed. For example, at peak hardness, the microstructure (Fig. 2*b*) was more characteristic of an aluminium–zinc–magnesium alloy. In most regions precipitate particles were small (average size 100 a.u.) and uniformly dispersed; dislocations generally had only a minor effect on precipitation (*A* in Fig. 2*b*). X-ray work showed that G.P.B. zones were formed at very short ageing times as for the silver-free alloy, but the second rise in hardness was associated with

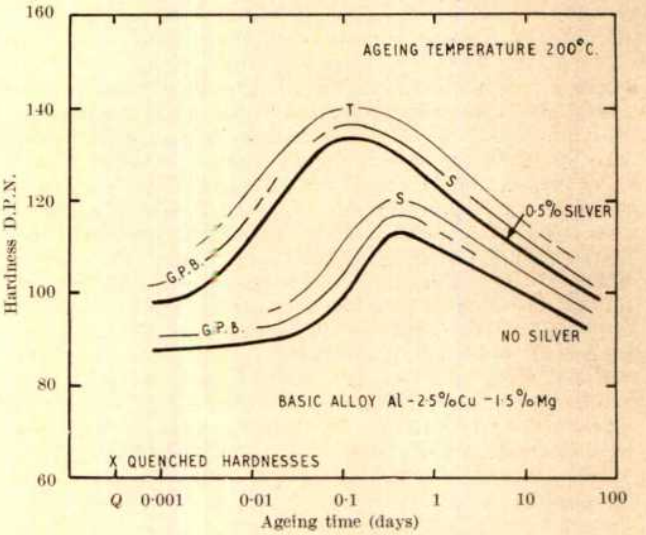

Fig. 1. Precipitate structures occurring at different parts of the hardness/time curves of aluminium–2·5 per cent copper–1·5 per cent magnesium, with and without 0·5 per cent silver, aged at 200° C

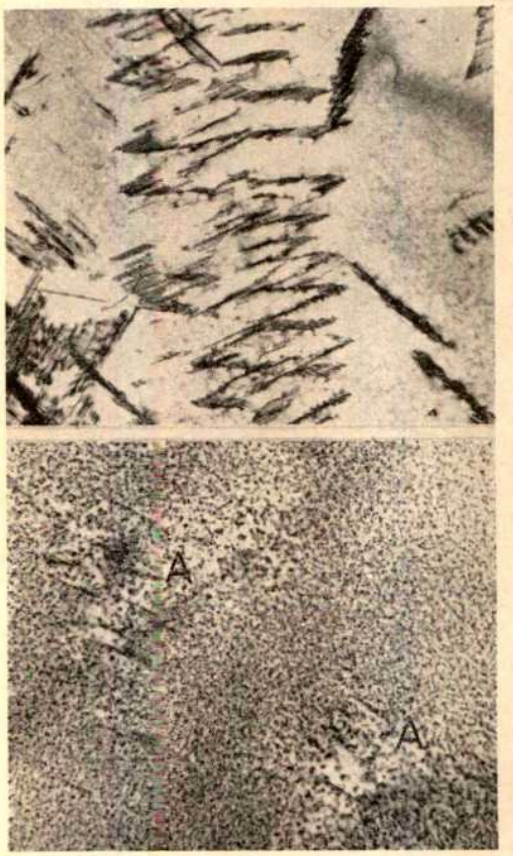

Fig. 2. Transmission electron micrographs showing the effects of 0·5 per cent silver on the microstructure of aluminium–2·5 per cent copper–1·5 per cent magnesium aged to peak hardness at 200° C: (*a*) No silver, aged 0·3 days; (*b*) 0·5 per cent silver, aged 0·15 days (× 37,500)

a T-phase structure. At peak hardness this T phase predominated and a small amount of S was detected. As softening occurred, the S phase increased as a uniform dispersion of lath-shaped particles and the T phase gradually decreased in amount. The S particles appeared to be nucleated homogeneously and were much finer than those present in the ternary alloy.

The effect of silver in promoting T-phase precipitation may be related to the fact that small amounts of silver stimulate hardening in aluminium–5 per cent magnesium by precipitating an equilibrium T phase, approximately Al_6 Ag Mg_4, as we have found, and which was reported recently by Wheeler *et al.*[10]. In the present work, using molybdenum radiation, the X-ray reflexions from the small particles were too diffuse to enable us to decide whether the T phase is this compound or Al_6 Cu Mg_4.

Another observation was that the peak hardnesses of the silver-free and silver-containing alloys were closer than might be expected from the marked contrast in the appearance of the precipitates. This hardness difference was even less at longer ageing times when there was still a marked disparity between the size and dispersion of the lath-shaped S particles. This suggests that the ability of dispersions of this kind to retard dislocation movements during plastic deformation is relatively insensitive to the size of the particles. The results may also have practical implications in view of the fact that aluminium–2·5 per cent copper–1·5 per cent magnesium is the age-hardening component of several commercial alloys used for elevated temperature applications. All these aspects are being investigated in more detail.

We thank Mr. B. E. Williams for his contribution to the experimental work.

Enhanced Diffusion Rates during the Fatigue of Metals

Enhanced diffusion rates during plastic straining or fatigue testing have been the subject of controversy for some time[1]. Conclusive evidence of this phenomenon, notwithstanding an estimate of the effect, has not yet been achieved. However, an investigation recently conducted on the fatigue properties of certain copper alloys at room temperature under unique conditions has allowed confirmation of changes in diffusion rate and also a measure of this change.

Fatigue tests have been conducted on oxygen-free high-conductivity copper specimens possessing a surface-alloyed layer of silver to a depth of 90 μm; the silver concentration varied from approximately 4 per cent at the surface to zero at 90 μm. Specimens were tested in a Wohler-type fatigue machine, operating at 2,880 c.p.m. at a stress-level giving a total life of 10^7 cycles. After failure, sections were taken to allow measurement of the radial distribution of the silver by means of a 'Cameca' electron-probe microanalyser. Comparison with blanks prepared under identical conditions, but not fatigue tested, revealed a significant difference in the silver concentration and penetration and showed the diffusion rate during fatigue to be considerably increased. Calculation shows that the diffusion activity in the fatigue specimen was equivalent to that which would have occurred had the specimen been simply heated to 300° C for the duration of the test, namely, 60 h. Several microanalyser traces were taken in different grains to allow for the orientation dependence of the diffusion process and the averaged results are displayed in Fig. 1.

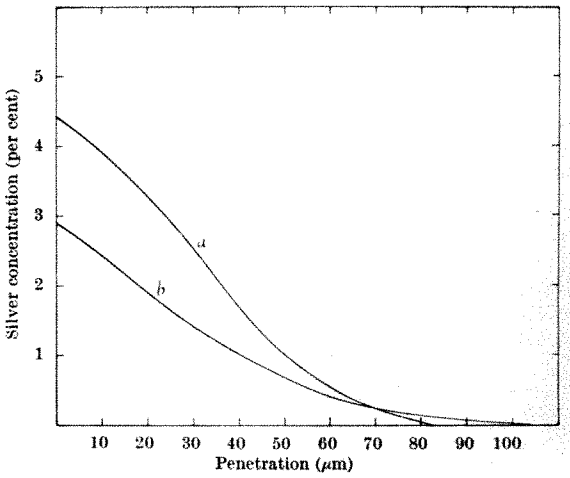

Fig. 1. Penetration curves for silver in copper before and after fatigue testing. *a*, Normal; *b*, after fatigue testing

Normally, long-range diffusion phenomena do not occur in copper at room temperature because the concentration of vacancies in thermal equilibrium in the crystal lattice and also the jump frequency are too low to facilitate appreciable movement of the atoms. The explanation of this phenomenon would appear to lie in the abnormally high vacancy concentration being produced during fatigue. The presence of a concentration gradient of silver in the surface layer of the copper has given directionality to the increased atomic movement and enabled a measure of this effect to be made.

Previous attempts[2] to measure an enhanced diffusion rate due to plastic deformation have been pursued in tests at temperatures well above room temperature where normal thermal diffusion rates have been appreciable. It is considered that the much larger rates of diffusion in these tests overshadowed the changes produced due to excess vacancy concentration and led to the confusion regarding the occurrence of this phenomenon.

The results obtained here are in keeping with observations made in irradiated materials[3] where diffusion changes have been detected and the cause been attributed to excess vacancy concentration. These measurements were achieved by detecting changes in short-range phenomena, such as ordering in certain alloy systems, and showed a similar equivalent temperature dependence.

The importance of this type of measurement lies in the fact that this is the first method yet realized where measurement of the mobility of atomic defects, important to the fundamental mode of fatigue failure in metals, has been made possible and should allow eventually a physical description of the process leading to crack initiation during fatigue.

CRYSTALLOGRAPHY

Crystalloluminescence

RECENT advances in the analytical techniques applied to the study of faint light sources have made it possible to investigate the nature of the light emitted during processes as diverse as crystallization, nucleation, cracking and various chemical reactions.

The crystalloluminescence observed during the nucleation of alkali halides is now well understood as an impurity phenomenon associated solely with three-dimensional, that is, homogeneous, nucleation[1]. Each pulse, several hundreds of photons in size, is emitted as the result of a single nucleation event. A nucleus of critical size, which forms as a disordered, glassy aggregate, eventually 'clicks' over into crystalline form within a few nanoseconds. The energy released during this phase change is converted into fluorescent light with high efficiency provided that suitable heavy-metal impurities are present to act as fluorescent centres. The development of nanosecond pulse techniques has enabled this mechanism to be examined in great detail. Crystalloluminescence, which thus accompanies the birth of a crystal, however, is a comparatively rare phenomenon, and it confirms the validity of Volmer's equation of the rate of homogeneous nucleation as will be shown in a forthcoming publication.

Another phenomenon, described as triboluminescence, is known to occur in numerous solid systems[2]. It is associated with electrical discharges across freshly formed gaps when certain solids are subjected to mechanical or thermal stress, the best-known examples, perhaps, being chlorates, bromates and mixed sulphates, all of which emit light on crystallization, and also ordinary sugar and saccharin, which both show luminescence when crushed. The energy released on cracking need not, of course, be emitted entirely as the long, irregular pulses characteristic of triboluminescence, but may also be converted to fluorescence and phosphorescence (random emission of single photons) in the presence of suitable impurities. Triboluminescence and the crystalloluminescence described in the foregoing are thus basically not related in any way to each other, the first being due to a corona discharge while the second is caused by a molecular rearrangement in which the released energy is converted into light by a mechanism akin to piezoluminescence. Crystalloluminescence shows marked regularities in time and pulse-size distribution depending on supersaturation whereas triboluminescence is invariably random in all respects.

There is a further source of light emission, which sometimes accompanies crystallization events and which appears to have caused some confusion in the past, namely, chemiluminescence. It is usually associated with free-radical recombinations (for example, it is easily observed during the homolytic oxidations of lucigenine, luminol and phenol) and it is also present in many autoxidations (for example, of benzaldehyde, aniline and oleic acid). Thus, the light observed many years ago during the crystallization of molten acetates[2] was not crystalloluminescence but it was due to free-radical activity caused by the thermally produced acetyl radical and its fragments[3]. Furthermore, chemiluminescence has more recently been detected[4] in the course of some heterolytic reactions from which oxygen emerges in the diamagnetic singlet state. As a rule, chemiluminescence can readily be distinguished from both triboluminescence and crystalloluminescence since the light is emitted randomly as single quanta. Nevertheless, it is often more difficult to separate chemiluminescence and low-level phosphorescence.

During the crystallization of non-ionizing organic compounds, the energy changes involved are insufficient to cause genuine crystalloluminescence and the light that is observed occasionally in such systems can be shown to be due to either triboluminescence or chemiluminescence

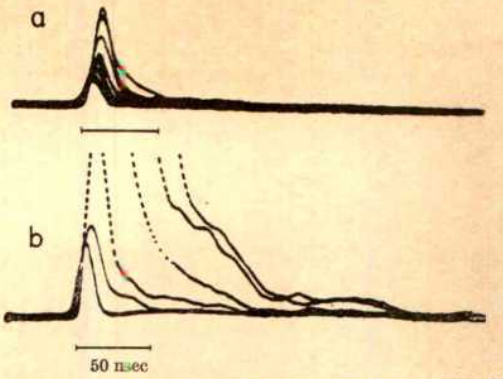

Fig. 1. Triboluminescence pulses observed during the crystallization of benzanilide from alcohol

or both. Thus we have found that the recently reported luminescence during the formation of benzanilide from aniline and benzoylchloride[5] is essentially caused by the cracking of those crystals appearing first (cf. Fig. 1), which form colourless phosphorescent leaflets and which, since Tschugaeff's time[6], have been known to be triboluminescent. The groups of triboluminescent pulses shown in Fig. 1*a* and *b* were photographed on 'Polaroid' 10,000 ASA using an oscillograph and associated amplifiers with a bandwidth of 75 Mc/s. The composite rise-time of the apparatus, including that of the multiplier photocell, was 9 nsec. The cell possessed a tri-alkali photocathode with a flat response from 1800 Å to 6500 Å and was cooled to −60° C.

Fig. 1*a* and *b* indicate, respectively, the lower and upper limits of the size range of the triboluminescent pulses obtained during the crystallization of benzanilide from various organic solvents. The larger pulses seen in *b* exhibit the irregularities typical of triboluminescence. Owing to a masking effect, much of the triboluminescent light is converted into phosphorescence which does not appear in the photographs but which can readily be observed at higher sensitivities. The fact that both types of pulses shown were due to triboluminescence (rather than to chemiluminescence, phosphorescence, or thermal emission from the photocathode) was confirmed by the detection of the electrostatic discharges, which are invariably associated with triboluminescence, by a method similar to that previously used by Belyaev *et al.*[7]. During both crystallization of benzanilide from solutions and its formation from benzoyl chloride and aniline in ether the multitudes of pulses observed varied randomly in size from 10 to 10,000 quanta.

The very high sensitivity of the techniques used in these laboratories allowed also the observation of a faint glow from the ethereal solutions of the two reagents as well as from pure ether itself. This weak light is, no doubt, due to very slight autoxidation of ether vapour, which may in turn induce secondary oxidation of the solutes.

The many pitfalls for the casual observer, who is likely to confuse one type of light with another, can be avoided by the use of apparatus of sufficient sensitivity and the means of distinguishing between pulses arising from single quanta and those of a more composite nature.

CHEMISTRY

Kinetics of the Reaction of Nitric Oxide with Molecular Oxygen

The results of detailed kinetic investigations of the reaction of nitric oxide with oxygen at a temperature of 25° C and partial gas pressures of 1–50 mm mercury demonstrate that this reaction does not exactly follow an equation of third order[1]. The formal third-order rate constant $k_{exp} = (d[NO_2]/dt)/[NO]^2 \cdot [O_2]$ calculated from reaction rates near the starting point of the reaction ($[O_2]$, $[NO] \gg [NO_2]$) depends on the composition of the sytesm: it follows from experimental data that k_{xp} does not depend only on the concentration of nitric oxide ($[NO]$) or that of oxygen $[O_2]$, but on their ratio $[O_2]/[NO]$ (Fig. 1). The relation $k_{exp} = k_{exp}$ ($[O_2]/[NO]$) decreases monotonously: within $[O_2]/[NO]$ values of three orders $dk_{exp}/d([O_2]/[NO]) < 0$, that is, $\partial k_{exp}/\partial[O_2] < 0$ and $\partial k_{exp}/\partial[NO] > 0$, which formally corresponds with a reaction order higher than 2 with respect to the concentration of nitric oxide and lower than 1 with respect to that of oxygen. This conclusion is in qualitative agreement with the results published by Treacy and Daniels[2]. For $[O_2]/[NO] \ll 1$, the limiting value of k_{exp} of $1{\cdot}48\ (\pm 0{\cdot}05) \times 10^4$ l.²/mol² sec was found; for $[O_2]/[NO] \gg 1$ this value is $0{\cdot}80\ (\pm 0{\cdot}05) \times 10^4$ l.²/mol² sec.

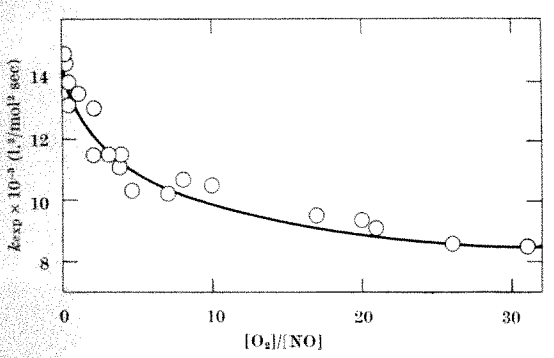

Fig. 1. Dependence of the formal third-order rate constant on the ratio of oxygen and nitric oxide concentrations

Heterogeneity of the reaction cannot be the cause of these deviations from third-order kinetics, as it has been established by differential calorimetry that the reaction under the conditions considered here is homogeneous[3]. The following mechanism of the reaction, agreeing with the relation of k_{exp} to $[O_2]/[NO]$ already mentioned, has been considered:

$$\text{(I)}\quad NO + NO \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} N_2O_2^*$$

$$\text{(II)}\quad N_2O_2^* + M \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} N_2O_2 + M$$

$$\text{(III)}\quad N_2O_2 + O_2 \xrightarrow[k_3]{} 2NO_2\ (\rightleftharpoons N_2O_4)$$

$$\text{(IV)}\quad N_2O_2^* + O_2 \xrightarrow[k_4]{} 2NO_2\ (\rightleftharpoons N_2O_4)$$

In reaction (I) the quasi-molecule of the dimer $N_2O_2^*$ is formed, which is stabilized in reaction (II) by molecule M, represented in this case only by a molecule of oxygen, O_2, or nitric oxide, NO. Assuming a stationary concentration of the stabilized dimer N_2O_2, the following equation can be derived for k_{exp}:

$$k_{exp} = 2K_1\left[k_4 + k_3\frac{k'_2[NO] + k''_2[O_2]}{k'_{-2}[NO] + (k''_{-2} + k_3)[O_2]}\right] \quad (1)$$

where $K_1 = k_1/k_{-1}$; k'_2, k'_{-2}, and k''_2, k''_{-2} are the rate constants of reaction (II) with $M = NO$, or $M = O_2$, respectively. According to this equation, k_{exp} is only really a function of the ratio $[O_2]/[NO]$; it follows also from equation (1) that the values of the constants k''_{-2} and k_3 must be comparable if deviations from a third-order kinetics are observable. It can be shown that this condition can be fulfilled if certain assumptions concerning the quasi-molecule of the dimer are made; however, the relatively low value of the probability factor of the reaction (I) must be considered. It follows from the quantitative evaluation of experimental data on the basis of the mechanism suggested that reaction (IV) may be neglected. The efficiency of the nitric oxide molecule in reaction (II), that is in stabilizing the quasi-molecule, is approximately six times greater than is that of the oxygen molecule.

According to the proposed mechanism, in the presence of the inert component M the constant k_{exp} would depend on the concentration of M and, in the case of a sufficiently high concentration, k_{exp} should be equal to $1{\cdot}48 \times 10^4$ l.²/mol² sec, regardless of the value of the ratio $[O_2]/[NO]$. This means that in a system with $[O_2]/[NO] \gg 1$ the value k_{exp} should rise with increasing $[M]$ to the value of $1{\cdot}48 \times 10^4$ l.²/mol² sec, whereas in a system with the ratio $[O_2]/[NO] \ll 1$ it would be actually independent of the concentration of the inert component. This assumption has been verified for $M \equiv CO_2$; the efficiency of the carbon dioxide molecule in reaction (II) is approximately forty times lower than that of the nitric oxide molecule. Therefore the positive effect of the inert component may only actually be observed in the systems with $[O_2]/[NO] \gg 1$ and $[M] \gg [O_2]$. The high efficiency of the nitric oxide molecule compared with those of oxygen and carbon dioxide is probably due to the ease of energy transfer in the exchange collision $N_2O_2^* + NO \rightarrow NO + N_2O_2$.

The proposed mechanism is therefore in qualitative agreement with the experimental data and does not lead to obvious discrepancies with known facts. An analogous mechanism with the intermediate ONOO instead of N_2O_2 leads to a kinetic equation which does not correspond with the experimentally found dependence of k_{exp} on the ratio of $[O_2]/[NO]$.

Phase Determination in Flame-sprayed 'Nickel Aluminide' Coating

'Nickel Aluminide' coatings ('Metco 404', Metco Inc., Westbury, New York, patents pending on the material and process) are manufactured by introducing aluminium particles jacketed with nickel into the flame of a spray gun. This powder then undergoes an exothermic reaction, and as a result of this heat evolution these coatings are self-bonding to many other materials. The producers claim[1,2] that the coating, flame-sprayed according to their instructions, consists mainly of NiAl, Ni_3Al and mixtures of these two. They claim further that they also have found some 'black oxide' of aluminium in the pores and voids of the coating.

The investigation reported here has, however, produced quite another result. An electron-probe X-ray microanalysis of such a coating revealed five distinct areas: (1) nickel metal phase; (2) aluminium metal phase; (3) a phase containing aluminium 12–17 weight per cent and nickel 83–88 weight per cent; (4) a phase containing aluminium 17 weight per cent and nickel 83 weight per cent (Ni_3Al); (5) a phase consisting of aluminium 55·2 weight per cent and no nickel (Al_2O_3) (especially around the edges of the pores as white 'needles'). In the micrograph (Fig. 1) the different phases are shown.

An X-ray diffraction analysis has further shown the presence of the phases Ni_3Al, nickel and aluminium with

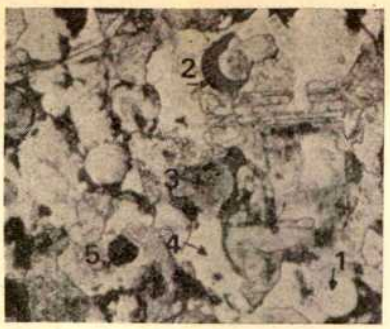

Fig. 1. 'Nickel Aluminide' coating after treatment 30 sec in 'Carapellas' reagent (×200)

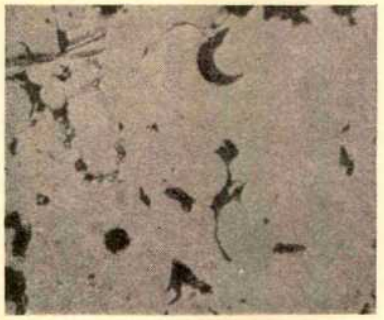

Fig. 2. 'Nickel Aluminide' coating before etching (×200)

traces of Al_2O_3 only. The lattice gratings of nickel have, however, considerably widened and lead to the result that apart from the Ni_3Al phase there exist phases consisting of a solid solution of aluminium in nickel.

It has further been claimed[1] that 'Carapellas' reagent (ferric chloride and hydrochloric acid in ethyl alcohol) attacks only NiAl and leaves Ni_3Al (see Figs. 1 and 2). In this investigation it has, however, been found that 'Carapellas' reagent attacks part of the areas with compositions up to the neighbourhood of Ni_3Al with the result that this etchant attacks phases with aluminium in solid solution in nickel but not crystallized Ni_3Al phases.

It can thus be seen that the exothermic reaction between nickel and aluminium in flame spraying guns is far from complete and gives no NiAl phase. It does, however, produce some Ni_3Al phase and also to some extent nickel phases with aluminium in solid solution to a concentration of up to 17 weight per cent.

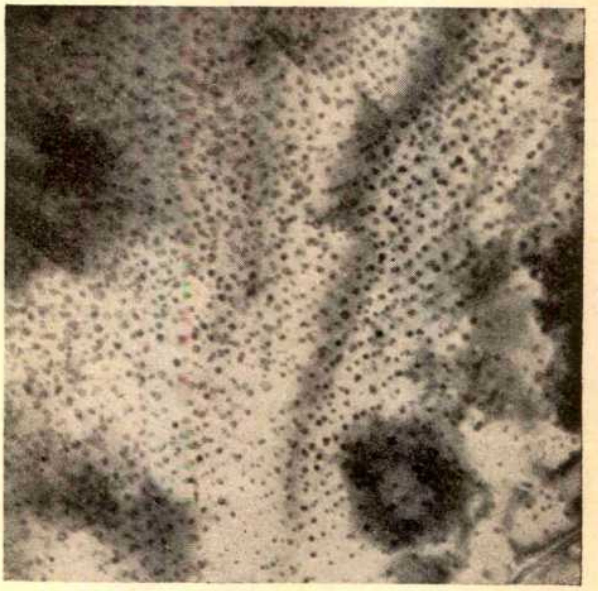
Detection of Magnetite as a Surface Impurity on Thin Foils of Ferrous Materials

FURSEY[1] recently reported that oxide films stripped from the surface of a specimen of mild steel immediately after electropolishing and washing were of the form Fe_3O_4. These films were shown to be barely visible and featureless when observed under high magnification in the electron microscope.

Over the past few months we have found that this oxide occurs on thin foils from a variety of low-alloyed steels and has also been observed on pure iron foils[2], but not on stainless steels. Although the oxide is not visible its presence is quite definite from the diffuse electron diffraction spot patterns that it gives. Subsequent examination of a 0·1 per cent niobium, 0·1 per cent carbon steel which was accidentally overheated in the electron microscope showed discrete particles on the surface of the ferrite matrix (Fig. 1). Diffraction analysis of these revealed the same pattern of reflexions as observed with the other steels but this time the reflexions were much sharper (Fig. 2).

We did not encounter the difficulty experienced by Fursey[1] regarding the identity of the diffracting medium. Although Fe_3O_4 and γ-Fe_2O_3 have virtually identical



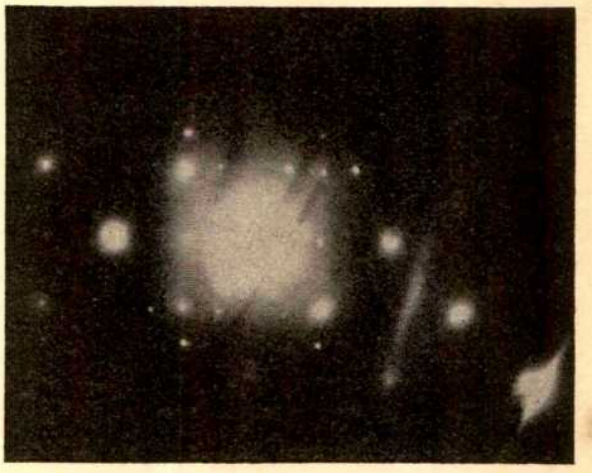


Fig. 1. Microstructure of a 0·1 per cent niobium, 0·1 per cent carbon steel after overheating in the electron microscope showing discrete oxide particles (×60,000)

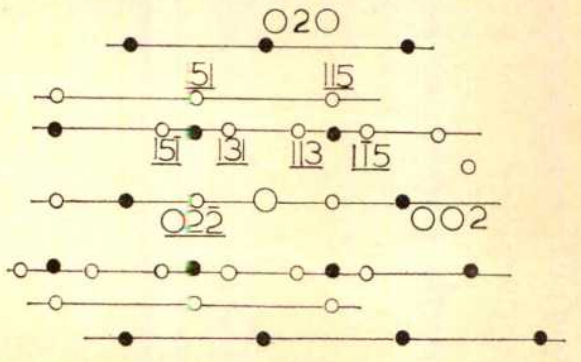

Fig. 2. Electron diffraction pattern taken from the area shown in Fig. 1. ○, *hkl*-oxide; ●, *hkl*-ferrite

lattice parameters and crystal structures, since the latter has a defect spinel structure, reflexions forbidden by the true spinel lattice will occur. Of these the {011} should be approximately 4/9 as intense as the {220} according to the *X-ray Powder Diffraction File* of the American Society for Testing and Materials[3]. Fig. 2 shows no evidence of this.

The oxide pattern comes from more than one crystallographic zone, namely $[\bar{6}11]$ and $[\bar{4}11]$. The zone axis of this is thus some 15° from the [100] zone observed by Fursey[1], and this pattern shows four of the {311} reflexions observed by her. The other four {311} reflexions are observed when the zone axis is tilted further away from the [100] so that the $[\bar{2}11]$ zone diffracts. Diffraction patterns are most commonly obtained from a range defined by the zone axes $[\bar{6}11]$ and $[\bar{2}11]$ (ref. 4).

It is likely that this oxide forms by atmospheric oxidation, the shortest exposure to air being sufficient to produce small areas. The diffuse spot patterns from it, the invisibility of it and its appearance on the overheated foil, suggest that it forms initially as a thin layer or as small disk-shaped particles, and that it will preferentially precipitate on ferrite grains which have a cube edge almost normal to the foil surface. The orientation relationship with the matrix will be published elsewhere[4]. It is reasonable to assume that the niobium steel already had a surface oxide layer before overheating in the microscope and that the effect of the heat was to cause growth of the oxide to give the discrete particles shown in Fig. 2.

Anodic Photocurrent and the Primary Process in Electrochemical Photoeffect

Anodic photocurrents are often produced when polarized metallic electrodes covered with oxide or other semiconducting material are illuminated in solutions[1]. The primary process is here the generation of a pair electron-hole, which results from the absorption of a light quantum in the surface layer.

A different kind of anodic photocurrent has been found in the case of a dropping mercury electrode illuminated by light not absorbed in the solution. This was observed in solutions of glyoxal, diacetyl, sodium oxalate, dimethyl oxalate, oxalic acid, pyruvic acid, glycine, Cl-acetic acid and a series of α-hydroxy acids. The condition of activity is apparently the presence of a $\rangle C{=}O$ group in the molecule with a negative substituent on the neighbouring carbon atom. In solutions of compounds giving polarographic anodic currents due to formation of complexes with mercury, such as ethylenediamine tetraacetic acid or ethylenediamine, the anodic photocurrent does not appear.

In a similar fashion to cathodic photocurrents on the dropping mercury electrode[2,3], anodic photocurrents are directly proportional to the surface of the electrode and to the intensity of light; the relation between the energy of the red limit of photocurrent and the potential of the electrode is linear (Fig. 1). However, unlike their effect on cathodic photocurrents, aqueous and ethanolic solutions yield anodic photocurrents of the same order of magnitude.

Since the absorption of light in the bulk of the solution has been excluded in the present experiments and since the absorption by the metallic surface should lead to cathodic photoemission of electrons, there is only one

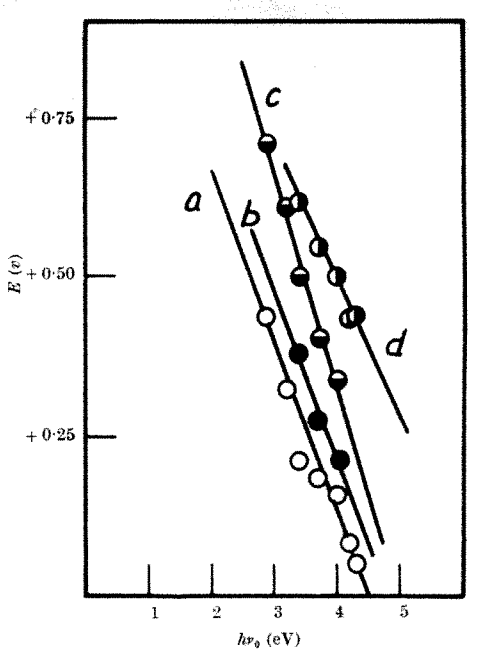

Fig. 1. Relation between the energy of red limit of photocurrent and the electrode potential in: (*a*) 0·1 M sodium tartrate in water; (*b*) 0·1 M oxalic acid in ethanol; (*c*) 1 M oxalic acid in water; (*d*) 0·1 M glycine in water. Potentials measured from the potential of zero charge

possible explanation—that the light-absorbing species responsible for the anodic photocurrent is a complex between the adsorbed organic compound and the surface of the electrode.

The mechanism of photoexcitation of such a complex can be interpreted in terms of the charge-transfer–no-bond theory applied to adsorption[4]. The electrode plays the part of an electron acceptor, the organic molecules are electron donors, and the adsorption bond corresponds to the ground state of the complex. On absorption of light quantum the electron is transferred from the adsorbed substance to the electrode. If the electron returns to the ground state, no direct current can be observed. The occurrence of a photocurrent indicates, therefore, that the complex in its excited state has undergone some secondary irreversible change. In the example given here, this change is probably an electrolytic oxidation of the dative state of the donor.

In solutions of sodium oxalate, for example, judging from the photochemical behaviour of oxalate complexes of mercury[5], it can be assumed that from the oxalate anion in the dative state the oxalate radical-anion $C_2O_4^-$ is formed which, as a strong reducing agent[6,7], is readily oxidized on the electrode to carbon dioxide, thus yielding the anodic current.

The photoexcitation of a charge-transfer complex between the electrode and an adsorbed substance might also explain the primary processes in the cathodic photocurrent in cases where direct emission of electrons is not likely to occur, as it has been observed in aqueous solutions[2,3].

BIOCHEMISTRY

Anomalous Dispersion of the Faraday Effect in Haemoglobin and Myoglobin

THE Faraday effect, namely, the magnetic rotation of the plane of polarization of light, was discovered in 1846 (ref. 1). However, except for Shashoua's studies[2,3] the anomalous dispersion of the Faraday effect in the polyatomic molecules has not been extensively investigated. Valuable information concerning the nature of electronic levels of molecules and macromolecules, and their configuration and conformation, can, in fact, be obtained from the anomalous dispersion of the Faraday effect[4–9]. The Faraday effect is closely connected with the Zeeman effect (see, for example, ref. 9); it is well known that the Zeeman effect plays an important part in spectroscopy, in the investigation of the structure of atoms and other polyelectronic systems. There are good reasons for suggesting that the anomalous dispersion of the Faraday effect is very susceptible to any change of the molecular structure.

We used as the first substances for our investigation horse haemoglobin (Hb) and the dolphin myoglobin (Mb). The ultimate purpose of this work was to study the co-operative properties of Hb considered as the model of an allosteric enzyme. Earlier we studied the anomalous dispersion of the natural optical activity in the absorption bands of Hb, Mb and their oxygenated forms[10].

We used a spectropolarimeter with an autocollimative quartz monochromator, utilizing polarizing prisms made from Iceland spar with a layer of molten quartz. The modulation was performed in a Faraday cell with the molten quartz rod. A magnetic field strength of 11,500 gauss was used, and the path length in the substance was 100 mm. The slit width was 0·2 mm. The light source used for emission in the long wave-length region was an incandescent lamp, and in the short-wave-length region a xenon lamp. The mean standard deviation in the measured rotation angles was ± 0·001°.

The substances were studied in 0·1 M phosphate buffer, *p*H 7·0. The concentrations for the measurements in the long wave-length region varied from 0·09 to 0·16 per cent, and for the short wave-length region from 0·018 to 0·031 per cent.

In Fig. 1 are shown the curves for the anomalous dispersion of the Faraday effect together with absorption curves for Hb and oxygenated Hb (HbO_2) in the long wave-length region. In Fig. 2 analogous curves are shown for Mb and MbO_2. In Figs. 3 and 4 the same data are given for the short wave-length region—for the Soret band. (The natural optical activity[10] has already been subtracted.) Hb is characterized by a complex curve of the anomalous dispersion of the Faraday effect with two minima in the absorption band 556 mμ. It is difficult to make any definite conclusions concerning the type of the two components of this complex curve before a more

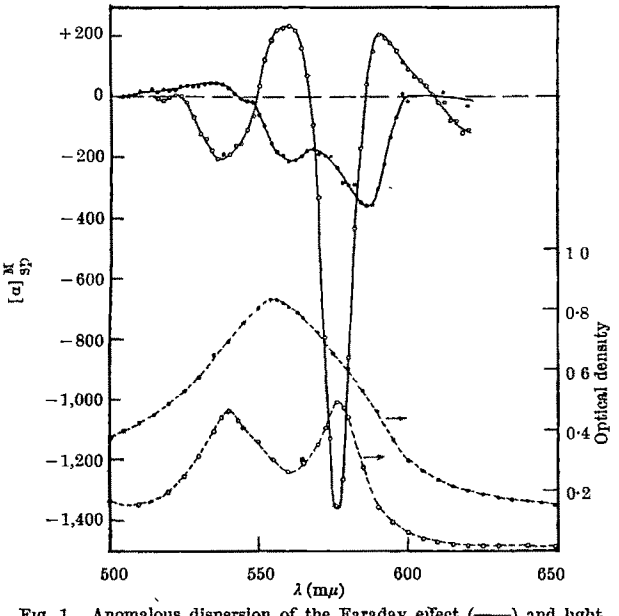

Fig. 1. Anomalous dispersion of the Faraday effect (——) and light absorption (- - - -) for Hb (●) and HbO_2 (○). $[\alpha]^{M}_{sp}$—specific magnetic rotation at 10,000 gauss

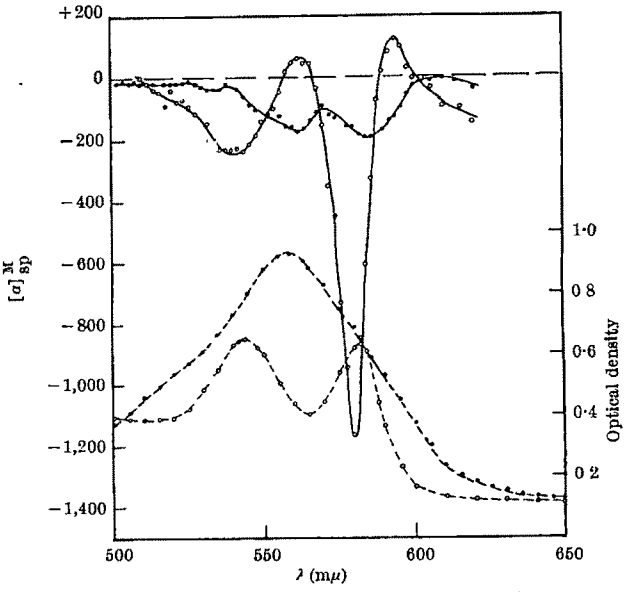

Fig. 2. Anomalous dispersion of the Faraday effect (——) and light absorption (- - - -) for Mb (●) and MbO_2 (○)

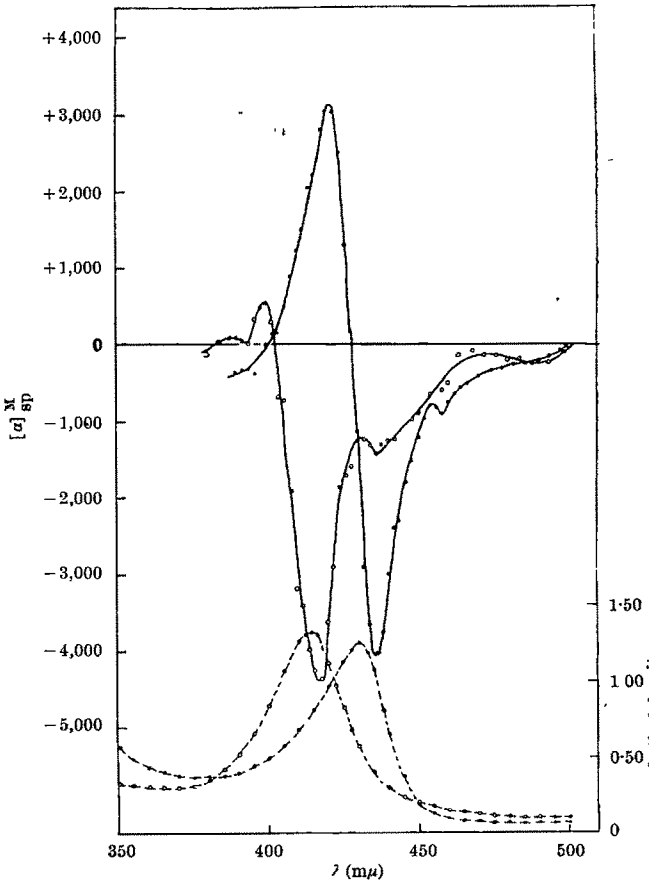

Fig. 3. The same curves as at Fig 1 but for the Soret band

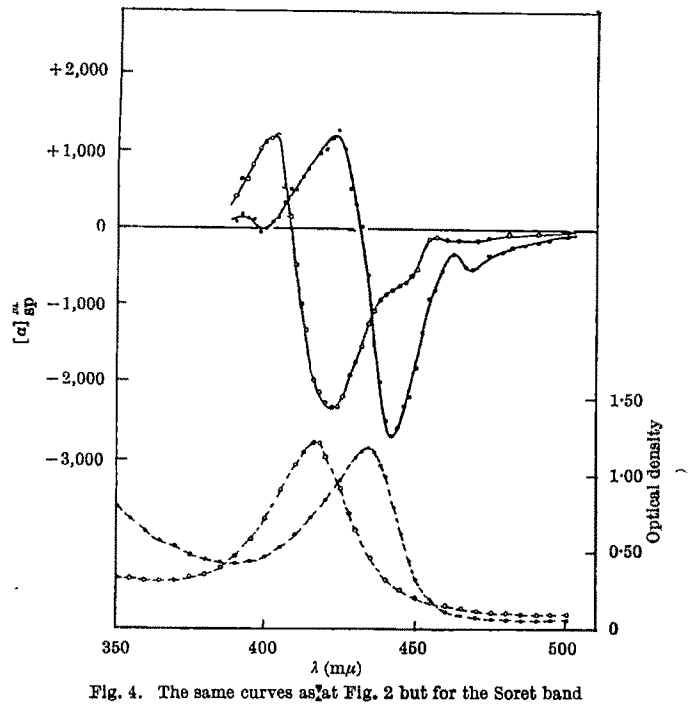

Fig. 4. The same curves as at Fig. 2 but for the Soret band

detailed analysis has been performed. However, the negative value of rotation in the whole region from 500 to 600 mμ suggests that both simple curves correspond to the symmetrical type, that is:

$$\theta_i = \frac{A_i}{(\nu_i^2 - \nu^2)^2} \qquad (1)$$

In the Soret band a much stronger effect is observed—an asymmetrical curve of anomalous dispersion of the Faraday effect corresponding to:

$$\theta_j = -\frac{|B_j|}{\nu_j^2 - \nu^2} \qquad (2)$$

The amplitude of the anomalous dispersion of the natural optical activity in this band is also much greater than in the long wave-band[10].

Without carrying out investigations on the temperature dependence of the anomalous dispersion of the Faraday effect it is difficult to say whether this kind of dispersion is determined by the paramagnetism of the molecule or by the electronic transition corresponding to the paramagnetism, independent of the temperature (the Van Vleck term in the diamagnetic susceptibility[5]). Investigations of the anomalous dispersion of the Faraday effect makes it possible, in principle, to determine the magnetic properties of the electronic levels of the molecules.

The oxygenation of Hb means the transition from the paramagnetic into the diamagnetic form. In all three absorption bands—α, β and Soret band—of HbO_8 the symmetrical curves of type (1) are observed. This is the Macaluso–Corbino effect[9,11], which corresponds to the simple Zeeman effect and therefore to the usual diamagnetism[5,9].

The curves of the anomalous dispersion of the Faraday effect for Mb and MbO_2 are qualitatively similar to the corresponding curves for Hb and HbO_8; however, well-pronounced quantitative differences are observed. It is possible that their interpretation, which will be done later, will give important information concerning the difference of the properties of the haem group included in the molecules of Mb and Hb, and MbO_2 and HbO_8.

If Mb is transformed by oxidation into the ferri-compound, the anomalous dispersion of the Faraday effect in the Soret band changes in a regular way. On one hand, the mininum near 440 mμ becomes smaller, while on the other the minimum near 410 mμ increases. In this way investigations of the anomalous dispersion of the Faraday effect make it possible to study the kinetics of the oxidization of the haem-containing protein and also of the oxygenation. Similar results were obtained by Shashoua[3], who studied cytochrome *c*.

We thus see that the anomalous dispersion of the Faraday effect is really very susceptible to changes in the molecular structure.

Further quantitative studies of the anomalous dispersion of the Faraday effect in Hb and Mb are in progress.

We thank Prof. M. I. Kornfeld and Dr. B. P. Atanasov for valuable help.

Nature of the Free Amino-acid Pool in Avian Tissues

In an earlier report from these laboratories[1] we demonstrated significant diurnal changes in protein, nucleic and seven free amino-acids of liver during the active involvement stage of a mild Newcastle disease virus (NDV) infection in chicks. The investigations have now been extended to include a comparison of liver and serum levels of these parameters during the incubation stage of NDV.

Procedures for the care and NDV inoculation of some 400 4-week-old chicks, fed a standard diet, and biochemical determinations of the tissues were the same as those previously described[2]. Killing and tissue sampling of control and infected chicks started at the time of inoculation and continued at specific intervals over the 72-h incubation period of the NDV. Statistical analyses were those of Snedecor[3].

All values for the liver were first computed in terms of μmoles/mg DNA as an estimate of cellular levels. For comparative purposes, the sum total of the seven liver free amino-acids determined were designated the 'free amino-acid pool' and the percentage of each free amino-acid in the pool was calculated. In the case of the sera, the percentage of each free amino-acid in the total of the seven was computed from values expressed in terms of μmoles/ml.

Fig. 1 shows the data for the liver. Within and between the control and infected groups there were significant ($< 0{\cdot}05$–$0{\cdot}01$) changes in free amino-acid pool size which were related to sampling hour and to infection. In spite of these fluctuations in pool size, there was a remarkable constancy in the percentage of each of the individual components. For example, while pool size for the controls changed as much as 40 per cent, the value for lysine remained between 10 and 12 per cent of the pool. However, these slight changes were significant ($< 0{\cdot}01$). Examination of the values for individual birds showed that variability in pool size was greater between chicks within sampling periods than variability in percentage of the individual amino-acids in the fluctuating pools. It

is of interest that the two non-essential amino-acids had somewhat higher variability.

Except for the first sampling period, 7 h after NDV inoculation, pool sizes of the control and infected groups showed significant ($< 0{\cdot}05$–$0{\cdot}01$) divergence at certain sampling hours. The daily average of the pool size over the 72-h period in the controls showed no trend, whereas in the infected groups there was a linear decline.

Similar data on the free amino-acids in the sera of the control and infected chicks are shown in Fig. 2. Here again there were significant ($< 0{\cdot}01$) within-day changes in the total quantity of free amino-acids. The curve of the infected groups was slightly higher than the controls, but fluctuations in both curves were related to sampling time and not to infection. As in the liver, the percentage of the individual amino-acids in relation to the total of the seven determined in the sera was remarkably constant.

Roberts and Simonsen[4] showed that in a given healthy species at a particular stage in its development, each normal tissue has a highly specific pattern of free amino-acids. The data presented here support these findings and, in addition, indicate that in spite of wide daily fluctuations in pool size not only the pattern but the quantity of free amino-acids in the pool is very uniform.

The data are further evidence that most phases of metabolism are maintained in balance by a homeostatic mechanism(s). This would be expected unless unusual stress occurs, since the free amino-acids reflect the average of the various pools which provide the *prima materia* to the different codes governing the synthesis of proteins. However, calculation of previously reported data[2] obtained during the active involvement stage of a severe NDV infection showed that NDV can change the make-up of the free amino-acid pool(s). In this case there were significant changes in the percentages of some amino-acids in the pool(s) which correlated with an increase in degree of disease involvement and a significant depression of body-weight.

Ubiquinone (Coenzyme Q) and the Respiratory Chain

UBIQUINONE (coenzyme *Q*, Co *Q*), a lipid soluble benzoquinone which is localized principally in mitochondria[1,2], has been shown to undergo cyclic oxidation-reduction during the oxidation of substrates of the citric acid cycle[3]. Kinetic investigations[4,5] of the redox reactions, however, have shown that its rate of reduction is insufficient to account for the total electron flux through the system. Treatment of mitochondrial particles with acetone, which extracts ubiquinone, has been claimed to result in a loss of electron transport activity which could not be restored without the addition of ubiquinone or one of its homologues[6]. These experiments showed that ubiquinone functions as an electron carrier in the respiratory chain, but while the kinetic data suggest that it has a position in a branch pathway[7], the extraction-reactivation experiments have been taken as proof of its obligatory involvement in a single sequence of electron transfer components[8]. In the course of a detailed investigation of the acetone extraction technique we have now obtained direct evidence that electron transport can occur in mitochondrial particles from which all the ubiquinone has been removed. This provides additional support for the concept

that electron transfer occurs through a branched chain system with one pathway dependent on ubiquinone and at least one other pathway in which ubiquinone does not participate.

The mitochondrial preparations used in these investigations were of the Keilin and Hartree type and were prepared from the pig heart-muscle by a method previously described[9]. In some cases the preparations were also made deficient in cytochrome *c* (ref. 10). The particles were suspended in 0·1 M Na/K phosphate buffer, *p*H 7·4, and extracted with acetone. Dry acetone was cooled to −15° and 75 ml. measured into a 100 ml. centrifuge tube. The mitochondrial particle preparation (3 ml.) was then added by drops to the acetone and the mixture stirred for 1–5 min. After centrifugation (3,000*g* for 10 min) the residue was extracted again with a further 75 ml. portion of acetone. The centrifugation and extraction were repeated and the residue was washed four times with 0·02 M Na/K phosphate buffer, *p*H 7·4. The final residue was suspended in 0·1 M Na/K phosphate, *p*H 7·4, using a Potter–Elvehjem homogenizer. Although it was found that the two extractions with acetone were sufficient to remove all the detectable ubiquinone in most experiments three extractions were made.

The complete absence of any detectable ubiquinone in these preparations was demonstrated. The lipids were extracted by the methods of Pumphrey and Redfearn[11] (including the treatment with sodium hydroxide to ensure complete dissociation of any tightly bound ubiquinone) or of Folch *et al.*[12] and then examined spectrophotometrically. The extracts were also subjected to a thin-layer chromatographic procedure[13] capable of detecting amounts of ubiquinone of the order of 0·25 μg, but in large-scale extractions the lipid extract was chromatographed on alumina before the spectrophotometric analysis and thin-layer chromatography. Although no trace of ubiquinone could be detected by any of these procedures, a small amount of a substance with absorption maximum at 276 mμ was isolated (Fig. 1). The slow disappearance of this peak on treatment with sodium borohydride and the lack of the appearance of a maximum at 290 mμ, coupled with its thin-layer chromatographic behaviour, ruled out the possibility that this substance was ubiquinone.

The reliability of the extraction and assay procedures was tested by adding to an acetone-extracted preparation an amount of ubiquinone equivalent to 0·18 μg per mg protein; it was found that more than 90 per cent of the added ubiquinone was recoverable. In a typical determination a three-times acetone-extracted preparation equivalent to 3 g of protein and containing originally 10 mg of ubiquinone was extracted but no ubiquinone was found. Since the method used was capable of detecting 0·1 per cent of the 10 mg of ubiquinone originally present and assuming that there is normally a ten-fold stoicheiometric excess of ubiquinone over the other respiratory chain components,

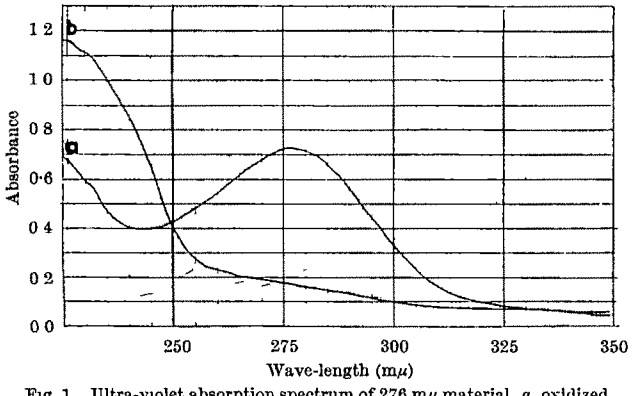

Fig 1. Ultra-violet absorption spectrum of 276 mμ material *a*, oxidized form; *b*, after reduction with sodium borohydride. Solvent, ethanol

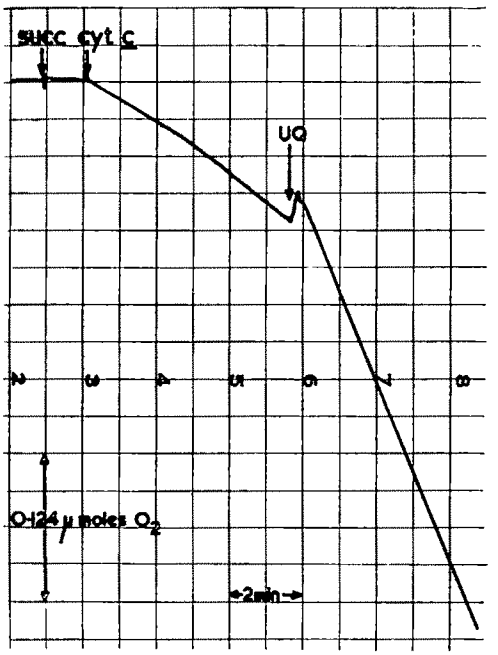

Fig. 2. Succinate oxidase activity of a three-times acetone-extracted heart-muscle preparation. Effect of addition of ubiquinone-15 and cytochrome *c*. Oxygen uptake measured polarographically with a Clark electrode at 20°

if any ubiquinone remained after acetone-extraction, it would be less than one-hundredth of the stoicheiometric equivalent amount.

Measurement of the succinate oxidase activity of the acetone-extracted preparations showed there was little or no activity. On the addition of cytochrome *c*, however, an appreciable activity was obtained (Fig. 2). The activity was further stimulated by the addition of a ubiquinone homologue such as ubiquinone-15 (*Q*-3). The oxygen uptake obtained in the presence of cytochrome *c* alone was completely sensitive to antimycin *A* and was equivalent to up to about 40 per cent of the activity after the addition of the ubiquinone homologue. These results are a clear indication that electron transport activity is proceeding in heart-muscle particles which are devoid of any detectable ubiquinone. D. E. Green and his colleagues have already shown that acetone-extraction induces a requirement for added cytochrome *c*, but in their experiments succinate oxidase activity could only be recovered by the addition of both cytochrome *c* and a ubiquinone homologue.

The demonstration that electron transfer could occur in ubiquinone-free mitochondrial particles raised the question as to which of the respiratory chain components were involved in this process. Spectrophotometric determinations indicated that both cytochrome c_1 and *b* become reduced on the addition of succinate to the acetone-extracted preparation (Fig. 3). There is, however, little or no reduction of cytochromes *a* and a_3. Addition of ubiquinone-15 to the preparation increased considerably both the rate and extent of reduction by succinate of cytochrome *b*. The results of an experiment on a three-times extracted preparation are given in Table 1. In this experiment, 13 per cent of the chemically reducible cytochrome *b* has been reduced by succinate. In the presence of ubiquinone-15 the extent of reduction increases to 26 per cent. Cytochrome c_1 appears to be much less affected by the addition of ubiquinone-15, but occasionally the rate and extent of reduction are increased. In the same experiment, the amount of cytochrome c_1 reducible by succinate in the absence and presence of added ubiquinone were 63 and 71 per cent, respectively. Cytochromes *a* and a_3 were reduced very slowly in the presence of added ubiquinone-15.

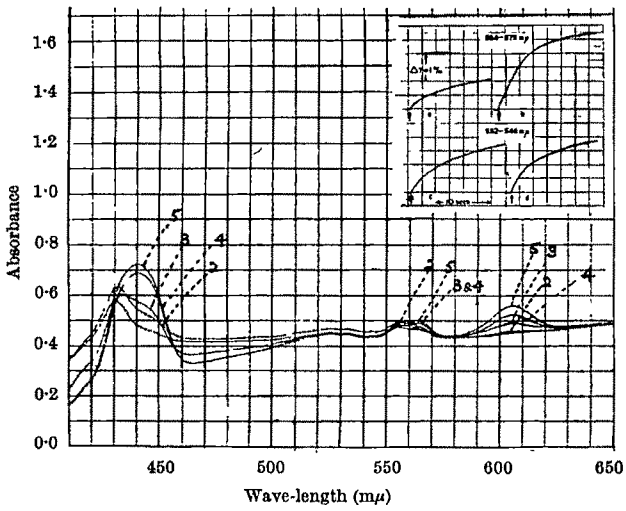

Fig. 3. Spectrophotometric determination of cytochrome reduction in a three-times acetone-extracted heart-muscle preparation. Difference spectra measured in a Unicam *S.P.* 800 recording spectrophotometer at 20°. 2, Spectrum after addition of succinate, 3, 1·25 min after addition of ubiquinone-15, 4, 6·25 min after addition of ubiquinone-15, 5, after addition of sodium dithionite. Inset shows rates of reduction of cytochrome *b* and cytochrome c_1, before (*a* and *c*) and after (*b* and *d*) addition of ubiquinone-15. Rates measured using Aminco-Chance dual wave-length spectrophotometer at 20°

Measurement of succinate–cytochrome *c* reductase activity showed that the rate of reduction of added cytochrome *c* was not the limiting step in the succinate oxidase system since the rate was higher than the overall oxygen uptake (Table 1). This suggests that the treatment with acetone has also caused some damage or disorganization in the cytochrome oxidase region of the chain.

In a recent article, D. E. Green[8] has stated that "the extraction and reactivation experiments provide unequivocal evidence for the obligatory participation of Co *Q* in the succinoxidase electron transfer chain", and he assigns a position for ubiquinone mediating electron transfer between the non-haem iron associated with the flavoproteins and the cytochrome *b* of the *b*-non-haem iron-c_1 complex. The present experiments, which have clearly indicated that electron transfer can occur in mitochondrial particles which are devoid of ubiquinone, invalidate this conclusion. It is clear from the present investigations that although ubiquinone is undoubtedly involved in the electron transfer process, it cannot be regarded as a component of a single sequence of components. In fact, there is already a considerable body of evidence from kinetic investigations[4,5] that ubiquinone is on a branched pathway of the electron transfer system. The activity obtained in the presence of cytochrome *c* alone probably represents a ubiquinone-independent pathway that is operating in the intact physiological system. It could be argued, however, that the acetone extraction has brought about an extensive structural disorganization so that artificial pathways are created. If the latter were the case, it is likely that the more drastic extraction procedure used by the Madison group would produce greater structural damage. The fact that they were unable to obtain activity with cytochrome *c* addition alone, and that no cytochrome *b* reduction could be observed in some of their extracted preparations[14], would suggest that the ubiquinone-independent pathway had been destroyed.

Table 1. Effect of Added Ubiquinone on Maximum Rates of Cytochrome Reduction and Oxygen Uptake in a Three-times Acetone-extracted Preparation

Cytochrome	Rate of reduction (μmoles/min/mg protein) In absence of Co *Q*	In presence of Co *Q*
b	0·00077	0·0019
c_1	0·0024	0·0039
c	0·08	0·26
Oxygen uptake*	0·014	0 046

The rates of reduction of cytochromes *b* and c_1 were measured in the Aminco-Chance dual wave-length spectrophotometer using the wave-length pairs shown in Fig. 3. Cytochrome *c* reduction was measured by the rate of increase of extinction at 550 mμ of added cytochrome *c*. Oxygen uptake was measured polarographically with a Clark electrode. All rates were determined at 20°.

* Expressed as μatoms oxygen/min/mg protein.

These experiments have again raised the question of the precise function of ubiquinone. The relative abundance of the quinone, its lipid solubility, the kinetics of its redox reactions and now the evidence that electron transfer can occur in its absence, suggest the possibility that ubiquinone may have another major function in addition to its role as an electron carrier.

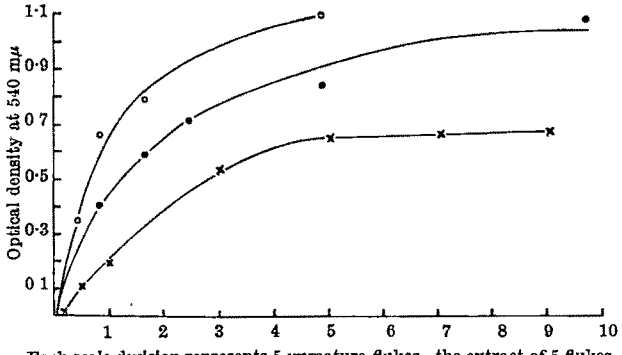
Collagenase Activity of Immature *Fasciola hepatica*

An essential phase in the life-cycle of many animal parasites involves extensive migration through the host tissue, and the concept of enzymatic mechanisms playing some part in this process is now generally accepted. This subject has been extensively reviewed by Lewert[1].

The mechanism of helminth migration is very similar to that following bacterial invasion, particularly *Clostridium welchii*, the toxin of which was shown[2] to contain a collagenase enzyme. The method for detecting collagenase activity developed by these authors is based on the release of bound dye from azocoll and has been applied successfully by Lewert and Lee[3] in their search for this type of enzyme in helminths, such as *Schistosoma mansoni* and *Strongyloides rattii*.

Until the present investigation a collagenase-type enzyme had not been demonstrated in the actively migrating immature fluke, although Boscardi and Coltorti[4] were able to show that the mature fluke does not possess mucinase, an enzyme sometimes associated with collagenase in helminths. However, from the evidence advanced by Dawes[5] on the tissue-feeding habits of young migrating flukes, it might be expected that these would have a need for a powerful external tissue-liquefying mechanism, which would not be necessary for the adult flukes since they are non-migratory residents of the liver bile ducts.

The need for immature flukes, in the work reported here, required a host animal from which they were readily available and, therefore, one in which they could be detected easily at a suitable stage in their development. For this reason the mouse was selected as the host, since it was found by Taylor and Parfitt[6] that this animal satisfied such requirements for short-term infections. A series of experiments was therefore performed in which mice were each infected orally with 10 metacercariae fo



varying periods of time ranging from 14 to 28 days. It was found that with the longer period of infection mice started to die after 23 days, very few surviving for more than 26 days. After 17 days most of the flukes had reached the liver and at this stage were approximately 2–3 mm in length; this appeared to be an ideal time for removing the flukes, since a shorter period of infection resulted in a reduction in the number recoverable.

After the mice were killed the livers were removed immediately and transferred to warm saline, where they were dissected by pulling the tissue apart rather than cutting, so as to minimize damage to the flukes. All those immediately visible were removed and washed with saline and in the meantime, provided that the residual liver tissue was maintained at 37° C, any flukes which remained unexposed initially soon migrated into view.

Originally, immature flukes collected in this way were extracted in 0·1 M sodium phosphate buffer *p*H 7·4 in an M.S.E.–Mullard ultrasonic apparatus, at 0° C for a period of 4 min. After removal of the fluke debris by centrifugation, the clear supernatant was tested for collagenase activity by incubating at 37° C with the azocoll substrate, prepared according to the method described by Oakley *et al.*[2]. Experiments were later carried out in which living immature flukes were incubated with azocoll immediately after removal from the host to determine whether enzyme activity was demonstrable without any previous physical extraction. This was an attempt to decide whether or not collagenase was actually excreted by the live organism into its environment.

The amount of dye released into solution from azocoll is proportional to the amount of collagenase activity present and Fig. 1 illustrates such a relationship resulting from the action of sonic extracts from varying numbers of immature flukes and similarly by living immature flukes on azocoll. The release of approximately equivalent amounts of dye brought about by known amounts of a *Cl. histolyticum* collagenase preparation (Sigma Chemical Co.) is also shown for comparison.

These results indicate that although an increase in either the amount of fluke extract or the number of whole flukes used gave a corresponding increase in dye release, this relationship was not linear and may be due in part to the amount of substrate being a limiting factor, since 24 whole immature flukes were sufficient to completely lyse 10 mg of azocoll in 2 h. The finding that an ultrasonic extract from a corresponding number of flukes did not produce such a high level of activity may be due to direct stimulation of the secretory glands of the living fluke by the azo dye, resulting in a more active enzyme complex being secreted into solution, as compared with physical extraction. Stirewalt[7] was able to demonstrate that immersion of *Schistosoma mansoni* cercariae into 'Pelikan' india ink induced a similar secretion of material from the acetabular gland complex.

Each scale division represents 5 immature flukes, the extract of 5 flukes, or 10 μg of *Cl. histolyticum* collag enase

Fig. 1. Activity against azocoll: 10 mg azocoll in 3·8 ml. 0 1 M phosphate buffer at *p*H 7·4, incubated 3 h at 37° C. ○, Live flukes; ●, sonic extract of flukes; ×, *Cl. histolyticum* collagenase

On the other hand, the reduced level of enzymatic activity when sonic extracts were used may have been brought about by enzyme inactivation as a result of oxidation effects produced by the ultrasonic vibrations, a phenomenon which has been investigated by Santamaria *et al.*[8] with mucinase activity, and which they prevented by including reducing agents.

The demonstration of collagenase activity in immature flukes would seem to indicate the presence of an efficient enzymatic penetrating mechanism, at a stage in the life-cycle when it requires to actively burrow through tissue. From the time it emerges from a cyst in the host's intestine until it reaches the bile ducts, the fluke first penetrates the intestinal wall and finally the liver mass, a journey which is accompanied by considerable tissue damage and inflammatory reaction[9]. There is evidence that the collagenase-like enzymes of *Schistosoma mansoni* cercariae are inhibited by substances present in the host's serum[10] and whether such inhibitors are produced as a result of a definite antibody response towards the parasite or, more simply, are non-specific substances arising from tissue damage remains uncertain. However, from his observations on the invasiveness of *Fasciola hepatica* weakened by X-irradiation, Dawes[11] is inclined to the view that local tissue reactions may be directed more towards the repair of damaged tissue than against the invading parasite. Further investigations on the anti-collagenase effect of such tissue reactions might help to elucidate whether this is antibody in nature or non-specific and, in addition, may reveal any significant reduction in the collagenase activity of the immature fluke, thereby preventing, or at least retarding, its migration.

Liquid Ion-exchange Extraction of some Physiologically Active Amines

Some long-chain alkyl phosphoric acids and long-chain alkylamines can be used as liquid ion-exchangers in a process analogous both to conventional ion-exchange with solid resins[1] and liquid-liquid extraction. The liquid ion-exchanger is dissolved in a water-immiscible liquid and partitioned with an aqueous solution of the ions to be separated. Extensive use has been made of this technique in the separation and recovery of inorganic cations, particularly heavy metal ions such as uranium.

Khim[2] has shown that nucleic acids and nucleoside phosphates can be extracted from aqueous buffer solutions by high molecular weight alkylamines in solvents such as amyl acetate and dibutyl ether. Dolinsky and Stein[3] have used a similar technique in an analytical procedure for extracting colouring matters from foods. This communication is concerned with the extraction of some organic bases from aqueous media using di-(2-ethylhexyl) phosphoric acid (DEHPA) in chloroform solution. There

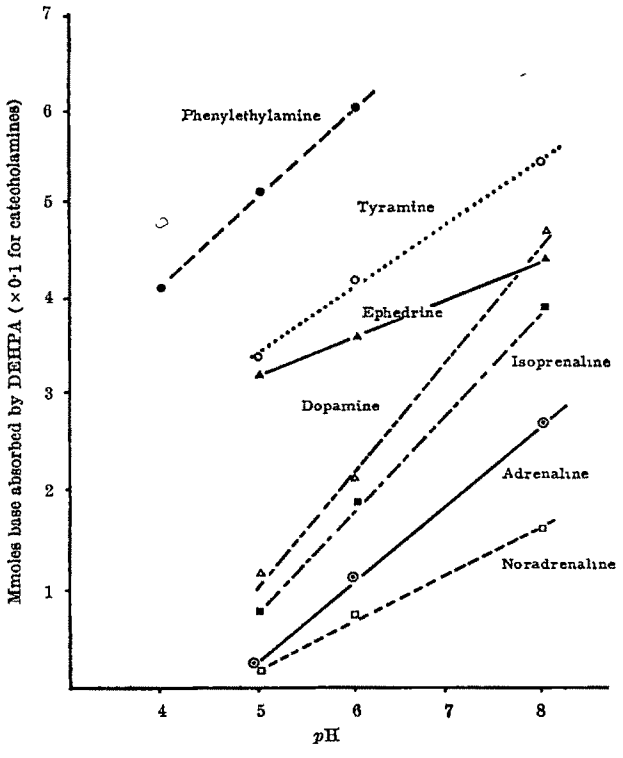

Fig. 1

appear to have been no reported separations of organic bases by this technique.

We have examined a series of physiologically active amines dissolved in citric acid/sodium phosphate buffer solutions[4] using 0·1 M DEHPA in chloroform. The results indicate that by appropriate variation of the *p*H of the buffer solution, mixtures of similar amines could be separated by the liquid ion-exchange process. The *p*H range of 4–8 was chosen to fall between the *p*K*a* values of the bases (9–11) and that of DEHPA (3·2), thus ensuring almost complete ionization of all the molecular species involved in the reaction.

The concentration of each amine in the aqueous solution before and after the ion-exchange reaction was compared by measuring the optical density at the λ_{max} for each compound. Each amine was dissolved in buffer solutions (diluted 1 : 10 to ionic strength 0·033) previously equilibrated with the DEHPA/chloroform solution, at three different *p*H values. The concentrations used were 0·1 mg/ml. for compounds having phenolic hydroxyl substituents and 1 mg/ml. for non-phenolic phenylethylamines, which produced optical densities in the range 1·0–2·0 at the λ_{max} for each amine (a Perkin–Elmer 350 ultra-violet spectrophotometer was used). An aliquot of each of these solutions, usually 5 ml., was shaken for 30 sec with an equal volume of 0·1 M DEHPA in chloroform, the phases separated by centrifuging for 5 min, and the change in concentration of the amine in the aqueous phase determined spectrophotometrically. Thus the concentration of amine extracted into the organic phase could be calculated over a range of *p*H values. The results (Fig. 1) indicate the existence of a linear relationship between the *p*H of the aqueous solution and concentration of amine extracted into the organic phase. It is possible at *p*H 5 to separate phenylethylamines, *p*-hydroxyphenylethylamines and catecholamines from each other by a very few stepwise partition reactions.

The amines can be readily converted to the aqueous phase by changing the *p*H; for example, more than 95 per cent of a sample of ephedrine was recovered from DEHPA solution by a single extraction with buffer at *p*H 2, and similarly noradrenaline at *p*H 3.

Table 1. PERCENTAGE OF BASE EXTRACTED BY DEHPA

*p*H	5	6	8
Dopamine	4	51	83
Isoprenaline	19	48	98
Adrenaline	8·5	39	89
Noradrenaline	6	24	52

The general tendency toward greater ease of extraction into DEHPA solution from catecholamines through tyramine to phenylethylamine (Fig. 1) may be explained by the possibility of intermolecular hydrogen bonding between phenolic hydroxyl and amino nitrogen groups which would sterically hinder the extraction of catecholamines and decrease the effective electron density on the amino nitrogen atom. The degree of extraction of each of the four catecholamines investigated was very *p*H-dependent, these drugs being not appreciably extracted at *p*H 5 and almost completely at *p*H 8 (Table 1).

The greater affinity for DEHPA of tyramine compared with dopamine may be further explained by the slight base-weakening effect of the meta-hydroxyl group discussed by Lewis[5] and Clarke and Perrin[6]. The addition of an alcoholic β-hydroxyl group in the side-chain reduces the basic strength of the amino group[5], which explains the relative ease of extraction of phenylethylamine (*p*K*a* 9·86) compared with ephedrine (*p*K*a* 9·49) and dopamine (*p*K*a* 10·63) compared with noradrenaline (*p*K*a* 9·78).

We thank Smith Kline and French Laboratories (Australia), Ltd., for financial support, and Prof. R. H. Thorp for his encouragement. We also thank the Stauffer Chemical Co. for a gift of DEHPA.

PHYSIOLOGY

Responses of Thalamic Neurones to Iontophoretically Applied Drugs

CLINICAL observations concerning the role of anticholinergic drugs[1] and ventrolateral thalamotomy[2] in the treatment of Parkinson's syndrome, together with histochemical investigations of the distribution of acetylcholinesterase in the thalamus[3], particularly in those nuclei relaying ascending reticular afferent fibres, suggest a possible transmitter-function for acetylcholine (ACh) in the ventrobasal thalamic nuclei.

To examine this question five-barrelled micropipettes were used to study the responses of 1,038 cells in the thalami of eleven cats. The centre barrel was filled with 4 M sodium chloride and recorded the electrical activity of single thalamic neurones extracellularly. One of the other four barrels usually contained 0·1 N hydrochloric acid for inducing lesions[4] and the remainder contained saturated solutions of the drugs to be tested by iontophoretic release into the immediate vicinity of individual neurones.

Cats were anaesthetized with pentobarbital sodium, fixed in a stereotaxic frame and the overlying brain tissue of one cerebral hemisphere was removed by suction to expose the fornix and floor of the lateral ventricle. Localization of the thalamic recording sites was accomplished by using as markers two stereotaxically oriented micropipettes inserted just beyond the lateral-most extent of the thalamus in the frontal Horsley-Clark planes *F*11 and *F*8 (ref. 5). These pipettes were inserted to a depth of 10

mm below the surface of the fornix, were cut, and left *in situ* to serve as markers during the experiment and for subsequent histology. Serial sections of the brain between and in the plane of the markers permitted precise localization of recording sites in relation to small hydrochloric acid lesions (Fig. 1*b*) placed at critical situations along most of the 63 micropipette tracks traversing the thalamus in these experiments.

The responses of thalamic neurones to iontophoretic application of ACh, using currents ranging from 10 to 120 n.amp, are summarized in Fig. 1*a*. The number of neurones fired by ACh in this way ranged between 1 out of the 43 cells identified in the n. lateralis dorsalis (LD) and 63 out of 101 neurones in n. ventralis posteromedialis/ventralis medialis (VPM/VM). It can be seen in Fig. 1*a* that neural excitation by ACh predominantly occurs in the ventrobasal thalamic nuclei, particularly in the ventral half of n. ventralis lateralis (VL), the medial part of n. ventralis postero-lateralis (VPL), and in VPM/VM. With the cell totals observed in each nucleus (see legend to Fig. 1) differences of approximately 10 per cent are statistically significant. The latency of the ACh-induced excitation was usually less than 15 sec (Fig. 1*c*), even in the case of the least sensitive neurones in which larger currents (60–120 n.amp) were used to apply the drug. There were many cells especially in the deepest thalamic nuclei which responded with high-frequency discharge at very short latency even to the minute amount of ACh released when the backing current was switched off. ACh-excited units generally occurred in vertical chains of several sensitive cells, but not infrequently ACh-insensitive neurones were encountered so close to ACh-sensitive cells that two clearly separable unit spikes of these opposite ACh sensitivities were recorded from one site. A type of response frequently found in cells excited by ACh comprised rhythmic burst discharges—similar to those described by Andersen *et al.*[6] as characteristic of the majority of thalamo-cortical relay neurones when stimulated either ortho- or anti-dromically.

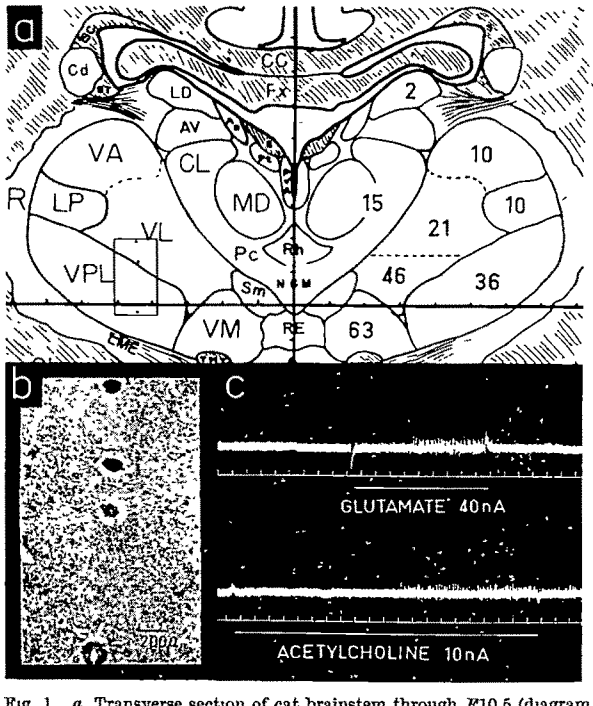

Fig. 1. *a*, Transverse section of cat brainstem through *F*10 5 (diagram and abbreviations after Jasper and Ajmone-Marsan (ref. 5)) Numbers on right-hand side are percentages of cells sensitive to ACh in various nuclei of the thalamus. Data from n centralis lateralis (CL) and n medialis dorsalis (MD) and also from n ventralis postero-medialis (VPM) and n ventralis medialis (VM) have been combined (since these last two nuclei occupy approximately corresponding ventro-medial locations through contiguous a.p. sections from *F*8 to *F*11). A broken line 1 5 mm above the Horsley-Clark zero has been used to divide the VL nucleus. Percentages are based on the following total number of cells in each case: LD–43; VA–116; LP–73, CL/MD–142; VL (above)–195, VL (below)–191; VPL–122; VPM/VM–101. *b*, Photomicrograph of VL and VPL nuclei in the region indicated by the boxed outline in *a*. The four lesions were formed by passing hydrochloric acid from the micropipette by iontophoresis. *c*, Recording of electrical activity of a unit 300μ below third lesion in *b*, showing response to 40 n.amp glutamate (upper) and 10 n amp ACh (lower) applied iontophoretically. The white line beneath unit records indicates the period for which the drug was applied. Time mark in sec

Other drugs were used in assessing the nature of the excitant action of ACh on thalamic neurones. These included carbaminoylcholine, acetyl-β-methylcholine, propionylcholine, butyrylcholine, nicotine, eserine, prostigmine, 'Tensilon', dihydro-β-erythroidine, hexamethonium, atropine and hyoscine. The most effective cholinomimetics were carbaminoylcholine and acetyl-β-methylcholine, and rather less excitation was produced by propionylcholine and butyrylcholine. Prostigmine and 'Tensilon' potentiated the effects of ACh, and in large doses they often excited. Excitation of most cells by ACh was effectively blocked by atropine or hyoscine; but dihydro-β-erythroidine was effective in preventing ACh-excitation in only six out of thirty cells tested. Hexamethonium also blocked the ACh-excitation of some cells.

From the pharmacological properties already described, most of the thalamic neurones excited by ACh seemed to be predominantly muscarinic in their responses. The few neurones which exhibited a more nicotinic response were often found to be less deeply situated in the ventrobasal thalamic nuclei.

It seems clear that a high proportion of neurones in the ventral basal thalamic nuclei VL, VPL and VPM/VM are excited by ACh. Andersen and Curtis[7] have also described the excitation of cells in the VPL nucleus by ACh and suggested that this might be related to a synaptic process.

The data presented in this report would be consistent with the presence of cholinergic synapses on cells in the ventral thalamic nuclei. Cholinergic afferent fibres may be derived from the ascending projection of cholinesterase-staining reticular fibres described by Shute and Lewis[3]. In addition, the presence of cholinergic cerebellar efferents in the thalamic nuclei is suggested by the observation that potentials evoked in the VL nucleus by stimulation of the brachium conjunctivum, which contains cholinesterase-staining fibres[8], have been abolished by atropine[9].

Prolonged Survival of Isolated Frog Muscle and its Sensitivity to Acetylcholine

In adult muscle fibres the membrane sensitivity to acetylcholine is restricted to the neuromuscular junction and its immediate surrounding[1]; but if the muscle is deprived of its motor innervation the entire muscle fibre surface becomes sensitive to acetylcholine[2,3].

It has recently been shown[4] that mammalian muscle can survive in organ culture, and that the fibres develop the generalized chemosensitivity even when kept in a completely synthetic medium. It was desirable to find out if similar results could be obtained from frog muscle as, for many experimental purposes, frog fibres are more convenient than mammalian fibres. One important drawback is that the development of acetylcholine-sensitivity

in denervated frog muscle kept *in situ* is very slow, several weeks having to elapse before the whole fibre becomes reactive to acetylcholine[3]. Our first step, therefore, was to find if frog muscle could survive in isolation for such a long period.

Frog sartorius muscles were dissected under aseptic conditions and mounted lightly stretched on nylon holders. Immediately after mounting, the muscles were placed vertically in individual culture chambers and immersed in about 25 ml. of culture fluid. The medium used was the chemically defined *TC*-199 (Difco) diluted to 50 per cent normal strength and with cation concentrations adjusted to: Na^+ 115 mM, K^+ 2·67 mM, and Ca^{++} 1·8 mM. Antibiotics added were chloromycetin 2 mg/100 ml. or penicillin 50,000 u./100 ml. and streptomycin 50 mg/100 ml. The medium was not oxygenated or stirred, and it equilibrated with air by way of a sterile cotton wool filter. The whole fluid was changed at approximately weekly intervals to counteract the effects of evaporation. The temperature was maintained near 20° C.

Muscle fibres kept in the culture medium were examined with intracellular microelectrodes, and were found to maintain normal resting and action potentials for about 2 weeks (Fig. 1*A*). A small segment of the motor nerve was usually left attached to the muscle, in order to test the state of the nerve-muscle junction. Neuromuscular transmission ceased after approximately 8 days: *in situ* controls kept at the same temperature failed at about the same time. After 3 weeks of culture the resting potential began to decline, reaching about 75 mV 1 month after isolation. The amplitude of the action potential also declined, but it still had an 'overshoot' and many fibres propagated action potentials and gave twitches (Fig. 1*B*) even at the longest culture period attempted so far (1 month). The muscles looked normal when examined under the light microscope and showed well-preserved fine structure under the electron-microscope.

The spatial distribution of acetylcholine-sensitivity was tested by micro-iontophoretic application of the drug to

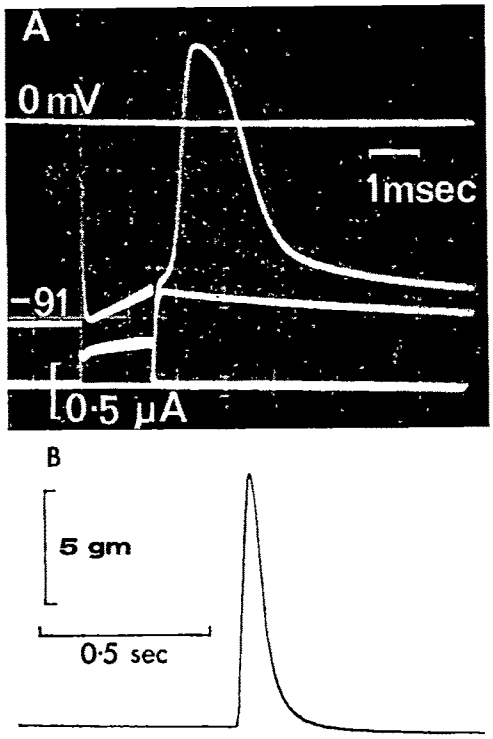

Fig. 1 Action potential and twitch recorded from frog sartorius muscle maintained in organ culture. *A*, Top trace, action potential evoked by intracellular stimulation, after 12 days of maintenance. Two pulses of different intensity were given. The first was just subthreshold, while the second evoked an action potential, bottom trace, stimulating current monitor. *B*, Muscle twitch after 27 days of maintenance

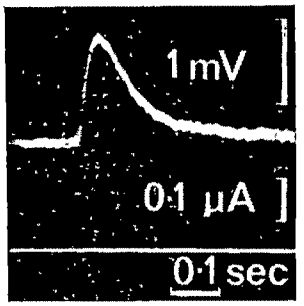

Fig. 2. Depolarization produced by micro-iontophoretic application of acetylcholine to a fibre in a muscle maintained in isolation for 27 days. The upper trace records intracellular potential while the lower trace monitors the current which flows through the acetylcholine pipette and releases the drug. Acetylcholine was applied at a point about 3 mm from the pelvic tendon, a region not normally sensitive to the drug

different parts of the fibre surface. The end-plate remains highly sensitive throughout the culture period. The regions, away from the end-plate, which normally are very insensitive to acetylcholine[5] developed the generalized sensitivity characteristic of denervated muscle. For example, in two muscles cultured for 27 days at 20° C, all the fibres tested at about 3 mm from the pelvic tendon were sensitive to acetylcholine (Fig. 2). The corresponding region had very low sensitivity in the normal control muscles. The mean sensitivity in the muscle kept in the culture medium was not very different from that of the corresponding region in denervated muscle kept *in situ* for the same time, and at the same temperature.

In contrast to the widespread distribution of acetylcholine sensitivity the cholinesterase remained visible with histochemical techniques, and had a normal distribution, being highly concentrated at the end-plate and myotendinous regions.

These experiments confirm the earlier observation[4] that muscles are intrinsically capable of developing acetylcholine sensitivity and that the induction of acetylcholine receptors is not dependent on the participation of other organs in the body.

Effect of a 'Fast' Nerve on 'Slow' Muscle Fibres in the Frog

Kuffler *et al.*[1–3] have shown that in the frog there are two very distinct types of skeletal muscle fibres; one, the more common, is capable of generating spikes and giving twitches; while the other is not. Further differences are that fibres of the spike type are innervated by fast nerve fibres and give only a transient contraction to maintained depolarization. On the other hand, when similarly stimulated, the non-spike type of muscle fibre produces a prolonged contraction. These 'slow' muscle fibres are multiply innervated by slow nerve fibres.

The question arises whether the different characteristics are imposed on the muscle fibres by the type of nerve fibre they receive. Buller, Eccles and Eccles[4] have already shown that the contractions of slow and fast mammalian muscles alter when their fibres are cross-innervated with nerves of the opposite type. In contrast, Feng *et al.*[5] have recently reported that a fast muscle of the chick does not change its speed of contraction when innervated by the nerve of a slow muscle.

The muscle fibres in the frog sartorius are fast (twitch) fibres, while the iliofibularis contains some slow fibres mixed among the twitch ones. In the experiments reported here, the mixed iliofibularis muscle was connected to the sartorius nerve, which normally innervates only fast fibres. To accomplish this, the sartorius muscle was removed from the left leg. The iliofibularis muscle from the right leg was then dissected, together with a small segment of its nerve, and placed in the left leg instead of the removed sartorius. The proximal stump of the sartorius nerve was then joined to the distal segment of the iliofibularis nerve in the transplanted muscle. With this operative procedure the possibility of innervation by aberrant motor nerve fibres is reduced to a minimum since the only muscle nerve cut in the left leg is the small sartorius branch. The muscles were examined 6–18 months after the operation. At this time the transplanted iliofibularis muscle contracted when the sartorius nerve was stimulated, and with intracellular microelectrodes most fibres examined were found to be innervated: they responded with an end-plate potential or an action potential to stimulation of the sartorius nerve. The regenerated neuromuscular junctions showed the properties previously described[6].

The normal iliofibularis and the remaining sartorius muscle were also isolated, and together with the transplanted iliofibularis they were set up for isometric tension recording. Prolonged depolarization of the normal iliofibularis muscle, with acetylcholine, produced the usual well-maintained contraction. On the other hand, in the iliofibularis innervated by the sartorius nerve, only a transient contraction was evoked. In two cases, the time course of this contraction was similar to that obtained in the normal sartorius muscle. In four others, as in Fig. 1, the contraction in the transplanted iliofibularis was somewhat more prolonged than in the fast sartorius muscle; but still clearly shorter than that of the iliofibularis innervated by its original nerve.

The absence of maintained contraction in these experiments could be interpreted as being due to a transformation of the slow fibres into twitch-like fibres due to the influence of the fast sartorius nerve; however, it could also be that the slow muscle fibres degenerate when the iliofibularis is innervated by the sartorius nerve. This second possibility is ruled out because electron-microscopic investigations of the transplanted muscles revealed normal muscle fibres which show the lack of *M* line in the thick filaments, and the special structure of the *Z* line both characteristic of slow fibres[7–8]. It is interesting to note that these structural features were still observed even 15 months after innervating the iliofibularis with the sartorius nerve.

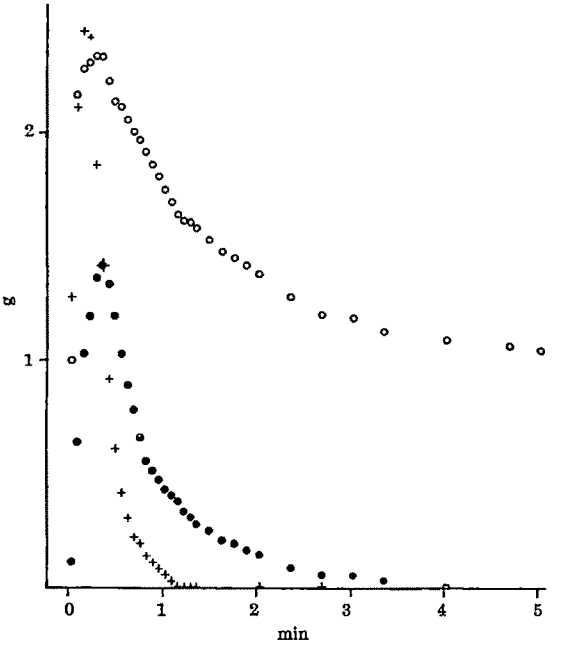

Fig. 1 Isometric contraction of transplanted iliofibularis innervated by sartorius nerve (dots); normal iliofibularis (circles), and normal sartorius (crosses). 13 months after operation done in August 1962. Abscissa: time after immersion of the muscle in a solution containing acetylcholine 2×10^{-5} g/ml. Initial tensions were 0·6 g and 0·65 g in transplanted and normal iliofibularis, respectively

In conclusion, the iliofibularis muscle can be transplanted and innervated by the fast sartorius nerve. The contraction due to prolonged action of acetylcholine is reduced in duration, but the electron-microscopical appearance of the *M* and *Z* lines in the originally 'slow' muscle fibres is not altered. Thus the ability of slow muscle fibres in maintaining tension for long periods does not seem to depend on these structural features.

PHARMACOLOGY

Synergism of Three Antimicrobial Drugs

Combined therapy with two or more antibacterial drugs may be useful in the treatment of an individual case, and in discouraging the development of resistance[1]. A formula was previously presented which could be used in evaluating the combined effect of two drugs[2]. An organism, highly resistant to penicillin alone and streptomycin alone, is often not affected by a combination of both, when they are combined at their attainable blood levels. In this instance addition of a third antibiotic may yield an inhibitory combination at concentrations of their respective blood levels.

Experiments were carried out with *Staphylococcus aureus* type 80 and Oxford strain, 46422. Each small test-tube contained 0·2 ml. 'Trypticase Soy Broth' (Baltimore Biological Laboratory), and was inoculated with 10^5 organisms. Presence or absence of growth was recorded after 18 h incubation at 37° C. In each experiment, three antibiotics were titrated separately, and simultaneously in different combinations. Results are summarized in Table 1.

Table 1. Mean Inhibiting Doses of Single Antibiotics*

Strain	No. of experiments	Single inhibitive dose			Combined inhibitive doses	Synergism
		Pen.	Strep.	Tet.	Pen. + Strep. + Tet.	
80	30	125	992	25	8 + 8·87 + 4	4 29295
46422	20	22·5	6,125	66 67	5 88 + 11·76 + 2 94	3·25372

Pen., penicillin; Strep., streptomycin; Tet., tetracyn.
* Units (Pen.) or μg (Strep. and Tet.) per ml.

We have endeavoured to determine the smallest amount of streptomycin needed (because of its toxicity) in combination with penicillin and tetracyn (tetracycline hydrochloride) for *Staphylococcus* 80. Penicillin and tetracyn were combined at fixed concentrations, 20 per cent below their attainable blood levels, with different concentrations of streptomycin. From thirty experiments the growth inhibitive combination was found to consist of: 8 u./ml. penicillin, 8·87 μg/ml. streptomycin and 4 μg/ml. tetracyn. For strain 46422 dilutions of the blood-level concentrations of the three antibiotics were

taken. The inhibitive combination proved to be: 5·88 U./ml. penicillin, 11·76 μg/ml. streptomycin and 2·94 μg/ml. tetracyn. All three antibiotics were effective in combination at 58·8 per cent of their respective maximum blood level concentration.

In line with former notation[2] it is assumed that a result of one indicates additive action, smaller than one antagonism, and greater than one synergism. In a mixture of three drugs, the dose of drug 'one', in combination, $D_{A_{1\ \mathrm{comb.}}}$, is usually smaller than its inhibitive dose, D_{A_1}, when acting alone. Thus the expression:

$$\left(1 - \frac{D_{A_{1\ \mathrm{comb.}}}}{D_{A_1}}\right)$$

is a measure of the space which is occupied by drugs 'two' and 'three'. As there are many possible partitions of this space between the two complementing drugs, a simpler approach was followed.

The full inhibitive dose forms the basis of all calculations. The combined effect of penicillin, streptomycin and tetracyn on *Staphylococcus* 80 should serve as an illustration. This organism is inhibited by 125 U./ml. penicillin, when acting alone, or by 8 U./ml. penicillin, when acting in combination with streptomycin and tetracyn. Thus streptomycin plus tetracyn reduce the need for penicillin to 8/125 = 0·064 of the inhibitive dose; likewise, the share of streptomycin in this combination is 8·87/992 = 0·00894 of the inhibitive dose, and the share of tetracyn is 4/25 = 0·16 of the inhibitive dose. All three drugs in combination exert a full inhibition by only 0·064 + 0·00894 + 0·16 = 0·23294 of the inhibitive dose. The reciprocal of this figure, 1/0·23294 = 4·29295, indicates the efficacy of the combination.

In general, let $D_{A_1}, D_{A_2}, D_{A_3}, \ldots D_{A_n}$ be the inhibitive doses of drugs, when acting singly, and $D_{A_{1\ \mathrm{comb}}}, D_{A_{2\ \mathrm{comb.}}}, D_{A_{3\ \mathrm{comb}}}, \ldots D_{A_{n\ \mathrm{comb}}}$, when acting in combination. The action of drugs in combination is estimated from:

$$\frac{1}{\frac{D_{A_{1\ \mathrm{comb}}}}{D_{A_1}} + \frac{D_{A_{2\ \mathrm{comb}}}}{D_{A_2}} + \frac{D_{A_{3\ \mathrm{comb}}}}{D_{A_3}} + \ldots \frac{D_{A_{n\ \mathrm{comb,}}}}{D_{A_n}}}$$

The foregoing expression leads to a conservative estimate, as it is most influenced by the drug, which is reduced least in a combination; in the example given, by tetracyn. The expression also makes it possible to estimate the efficacy of a combination with any number of participating drugs.

We thank Dr. R. L. Vollum, director of the Bacteriology Laboratory, the Radcliffe Infirmary, Oxford, for sending us strains.

Pharmacology of Akinesia—Investigations on 3,4-Dimethoxyphenylethylamine

AKINESIA in Parkinson's disease is a complex phenomenon which resembles catalepsy and includes a reduction in motor activity as well as a certain degree of catatonia (maintenance of a fixed passively imposed position). Akinesia as a clinical sign may be connected with changes in the metabolism of dopamine (DA), a substance involved in the pathogenesis of Parkinson's disease[1]. Experimental investigations in animals strengthen the evidence for a relationship between catecholamines and control of motility. Fisher and Lopez Amalfara[2] found that epinephrine (E) and norepinephrine (NE) caused a motor depression, while Ernst[3] produced a striking akineto-rigid syndrome in cats with injections of two possible dopamine metabolites: 3,4-dimethoxyphenylethylamine (DIMPEA) and 4-methoxyphenylethylamine (4-MEPEA), both structurally related to mescaline (3,4,5-trimethoxyphenylethylamine). These investigations gained further significance with the identification of DIMPEA in the urine of schizophrenic patients by Friedhoff and Van Winkle[4] and others since[5]. This same compound was found by Barbeau *et al.* in high concentration in the urine of clinically akinetic parkinsonian patients[6].

In order to study the pharmacology of akinesia and its production by compounds related to dopamine, objective and quantitative tests were chosen for their ability to measure, in experimental animals, the elements of 'fixity' and of spontaneous activity. 'Fixity' was evaluated with the 'traction test': a mouse holds a horizontal bar with the forepaws, while the rest of the body is suspended by the tail. When the tail is released by the experimenter, the lower part of the body springs forward; normal animals grasp the bar with the hindlimbs within 5 sec, while paralysed, cataconic or excited animals take a longer time, or fall. Total motor activity was measured in groups of five mice with an open field actophotometer (Woodard Research Corp.) equipped with six converging light beams.

Pilot studies with intraperitoneal injections of DIMPEA (K. and K. Laboratories) in doses ranging from 2 to 200 mg/kg body-weight produced akinesia in six rats, twelve mice, eight rhesus monkeys and four rabbits. This reaction was recorded by cinematography and resembled Ernst's observations in the cat[3]. Our animals slowed down for approximately 5–10 min after the injection and hesitated to initiate a change in position, yet reacted normally to stimuli. The speed of the actual movements was reduced as well. At doses of less than 100 mg/kg the animals were never sleepy. Catatonic activity in mice, as measured with the traction test in 15 groups of twenty animals, was evident at doses approaching 80 mg/kg. This phenomenon started 15 min and lasted 60–150 min after an intraperitoneal injection. At higher doses the animals were excited, occasionally trembled and most fell off the bar before completing the test. At doses above 200 mg/kg many animals convulsed and died.

Table 1. EFFECT OF DIMPEA ON MOTILITY
(Counts/10 min)

Group	N (groups of 5 mice)	$\bar{x}$	S	$S\bar{x}$	't' Drug/placebo	P
Placebo	12	841·9	260·1	75·0	—	—
1 mg/kg	12	879 3	273·2	78 8	0·60	N.S.
10 mg/kg	12	742·0	299·2	86 4	1·32	N.S.
50 mg/kg	12	399·5	213·4	61·6	4 27	<0·01
100 mg/kg	12	289·4	220 0	62·3	6·17	<0 01

Further experiments were designed to evaluate the effect of DIMPEA on motor activity. Twelve groups of five mice were randomly injected with each of five dosage schedules. Immediately after the injection the animals were placed in the actophotometer and, 5 min later, their activity was measured for a period of 10 min. Spontaneous activity was significantly reduced ($P < 0·01$) following injections of 50 and 100 mg/kg of DIMPEA (Table 1). The decrease in activity preceded the catatonic effect. The animals were slower within 5 min but could perform the traction test up to about 15 min after the injection.

Similar investigations were carried out at the standard dose of 100 mg/kg with a number of metabolites of dopamine (Table 2). For each drug, twelve groups of five

randomly selected mice were used. Dopamine decreased the motor activity of mice at 100 and 25 mg/kg. The metabolites behaved in various ways: 3-methoxytyramine was inactive when compared with a saline placebo, while 4-MEPEA caused a depression of motor activity quantitatively similar to that caused by DIMPEA. 3,4-Dihydroxyphenylacetic acid (DIMPAC) (the presumed oxidation metabolite of DIMPEA) is inactive as measured by this test. 3,4-Dihydroxyphenylalanine (DOPA), a precursor of dopamine, also produced a significant slowing of the animals. At doses above 200 mg/kg (not shown in Table 2) the animals receiving DOPA were excited, aggressive, but moved only in slow steps. Although DOPA given alone markedly reduced the activity of mice in the actophotometer, it also effectively prevented the cataleptic and akinetic effects of DIMPEA when given 30 min previously. This phenomenon was better observed in monkeys. The animals given DIMPEA after DOPA pre-treatment could easily initiate a movement (contrary to what is observed with DIMPEA alone), yet the movements were still slow in execution.

could not perform the traction test properly, mainly because they were so excited that they fell off the bar. These animals were not akinetic. After similar time intervals, the animals injected with DIMPEA or 4-MEPEA were slow and markedly akinetic in the traction test.

Chronic injections of DIMPEA at doses of more than 10 mg/kg/day over periods extending to 6 months in rats, rabbits and monkeys elicited a persistent akinetic syndrome. Histopathological study of the six chronically injected rhesus monkeys did not reveal lesions in the liver or brain, particularly the substantia nigra, striatum and globus pallidus. A diffuse discoloration of the brain was seen with the Klüver stains. Specific colour reactions for β-phenylethylamines[7] demonstrated a diffuse penetration of such a substance into the brain presumably across the blood–brain barrier. Mescaline, which is structurally related to DIMPEA, is known to cross the blood–brain barrier in a similar diffuse manner[8]. Thus, DIMPEA and 4-MEPEA appear to cross the blood–brain barrier in greater quantity than either E, NE or

Similar experiments could not be carried out with E and NE at equal doses because of their toxicity; but we confirmed that an intraperitoneal injection of 0·3 mg/kg of body-weight of these catecholamines produced a slowing of motor activity lasting 10–20 min, as previously reported. However, long-term observations in the actophotometer (Fig. 1) revealed that the action of these compounds was biphasic. After the initial depression of movements, there was a recrudescence of activity. The E- and DA-injected animals were more active after 30 min and 1 h than the placebo-injected controls. The NE-injected animals were very active at 30 min after the initial slowness, but resembled the control group at 1 h. In contrast, the animals receiving DIMPEA or 4-MEPEA remained constantly slower than the controls. At 30 min, 1, 1·5 and 3 h the animals injected with E, NE or DA

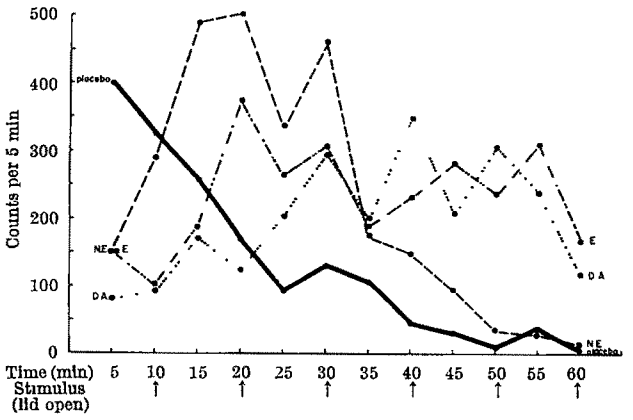

Fig. 1. Long-term actophotometer observation with catecholamines. ——, Placebo, – – – –, norepinephrine, —·—·—, epinephrine; . . . . . , dopamine

DA. The knowledge of this difference is important for the understanding of akinesia.

Indeed, akinesia, best defined as a difficulty or incapability of initiating movements, should not be equated with the so-called 'psychomotor depression' previously described with the catecholamines[2]. The actual effect of parenterally injected catecholamines on motility, as indicated by long-term observation in the actophotometer, is excitation. This is consistent with their selective penetration through the blood–brain barrier and their stimulating effect on the ergotropic systems in the hypothalamus and brain-stem reticular formation. The decrease of motor activity in the immediate post-injection period is not accompanied, in our experiments with the traction test, with 'fixity'. Probably it is related to a peripheral (non-brain) mechanism, perhaps a state of rigidity. In contrast, injections of DIMPEA or 4-MEPEA are always accompanied by both fixity and decreased motility.

If the phenomenon produced by DIMPEA and 4-MEPEA can be equated to akinesia, then akinesia would possess both a central and a peripheral component. In this light it is interesting to note that Smythies and Sykes[9] have recently shown that DIMPEA inhibits the conditioned avoidance response in rats. Motor activity measurements are thus not sufficient as a quantitative evaluation of akinesia or catatonia and, in further investigations, more attention should be directed to tests able to delineate the phenomenon of 'fixity' with its central components. It is our opinion that DIMPEA and 4-MEPEA are related to the symptom of akinesia in Parkinson's disease and that this action probably takes place through competition with the normal metabolism of dopamine in the central nervous system.

The investigations reported in this communication were carried out with the help of grants 604-5-124 and 604-5-125 from the Ministry of Health (Canada). We thank Dr. G.

Ledoux and Mr. A. Moreau, of Poulenc (Canada) Ltée, and Dr. L. Poirier, of the University of Montreal, for their assistance.

HAEMATOLOGY

A Naturally Occurring Foetal Haemoglobin Hybrid

Recent evidence[1] has shown that abnormal haemoglobins can result from the mutation of genes controlling the synthesis of α-, β- and δ-chains in the adult as well as γ-chains in the foetus. According to this concept, it should be possible for an individual to inherit simultaneously a gene for an α- as well as a β-chain abnormality. Such a person could possess eight haemoglobins: two completely normal (Hb-A and A_2), the abnormal α-chain with a normal β-chain ($\alpha_2{}^x B_2$), the normal α-chain with the abnormal β-chain ($\alpha_2 B^x{}_2$), both abnormal chains ($\alpha_2{}^x B^x{}_2$), the abnormal α- with the normal δ-chain ($\alpha_2{}^x \delta^2$), and finally the abnormal α- with a normal γ-chain ($\alpha_2{}^x \gamma_2$). One of us[2] has already discussed the occurrence of minor haemoglobins of cord blood and the relationship of Hb-H and Bart's to each other and to Hb-F.

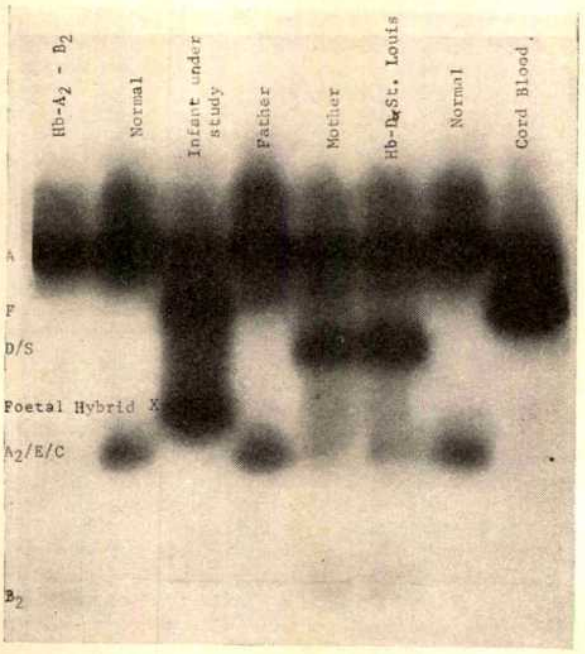

Fig. 1. Starch-gel electrophoresis of selected haemoglobin samples at *p*H 8·1 (*tris*-EDTA-borate buffer); benzidine stain

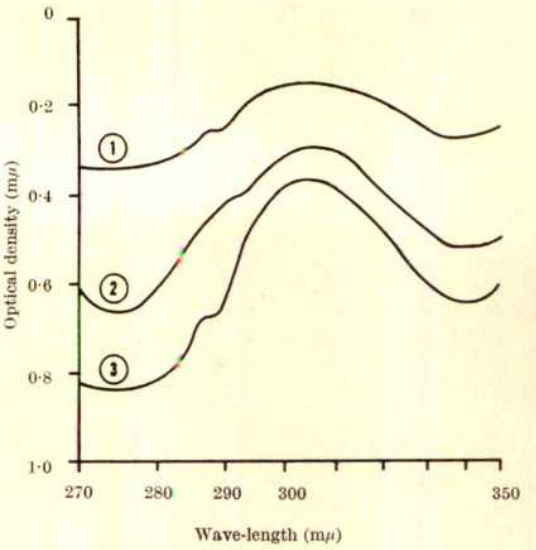

Fig. 2. Ultra-violet spectrum of eluates from DEAE cellulose chromatography. Slit width 0·1 mm, 1 cm cuvette. (1) Pure Hb-F; (2) pure Hb-A; (3) isolated slow foetal fraction *X* under discussion

We have investigated, using routine starch-gel electrophoresis, 1,373 haemoglobin samples from new-born Negro babies. Fifty-two (5 per cent) had Hb-Bart's, forty-three (3·1 per cent) had Hb-S trait, twenty-four (1·7 per cent) had Hb-C trait, while one each had Hb-Gower II, Hb-H and a slow-moving component resembling Hb-Alexandra. Less than fifty cord bloods were obtained on Caucasian babies and no abnormalities were seen. Because of the presence on starch-gel electrophoresis of a slower moving anodal component, in addition to the usual pattern F + A (Fig. 1), the following observations were made.

Comparison with known haemoglobin variants on starch gel at *p*H 8·0–8·6 (ref. 3) disclosed that this component was slower than Hb-S and only slightly faster than C, E or A_2. At *p*H 6·7 (phosphate buffer 0·1 M) this fraction moved rather like S. Hb-O (ref. 4) Alexandra[5] and the foetal component of Dα St. Louis[6] are the only variants known to occupy a position intermediate between C/A_2 and S at an alkaline *p*H. On DEAE cellulose chromatography[3], this slow-moving component occupied a position between Hb-A and S. By agar electrophoresis[6], only two spots corresponding to the positions of F and A were obtained, while a concentrate of the isolated fraction revealed only one spot at the position; such a position serves to distinguish it from Hb-D, which does not separate from Hb-A.

Foetal haemoglobin, as determined by alkali denaturation of the total haemoglobin haemolysate, was 61 per cent, approximately equal to the sum of the slow-moving fraction under investigation (17 per cent) plus the isolated pure Hb-F (42 per cent). The ultra-violet spectrum of the fraction under investigation showed the same tryptophan band at 289μ as Hb-F (Fig. 2). Quantitation of the amino-acid fractions of an acid hydrolysate by means of a five-column Technicon 'Autoanalyser' revealed an isoleucine : methionine ratio of 2 : 1.

The babies presented no clinical or haematological abnormalities. Of the parents, the father was normal, while the mother possessed a slow-moving haemoglobin shown to be Hb-D and, by further investigation, to be identical to Hb-Dα St. Louis (Fig. 1).

Hybridization[7] of the slow-moving component in the mother with isolated Hb-F resulted in the formation of a component similar to the slow-moving foetal fraction

under discussion which was thus the result of the combination of abnormal α- with normal γ-chains.

Our findings suggest that this foetal component is similar to that described by Fessas[5] as Hb-Alexandra, where only one normal parent was available for study, and with a component described by Vella *et al.*[8] in Malaya. In the latter case, the haemoglobins of both parents were said to be identical on starch-block electrophoresis although, in our experience, Hb-A_2 and B_2 may remain undetected if present in quantities less than 1 per cent. Recently, Minnich *et al.*[9] reported a foetal form of Hb-Dα St. Louis which resembles the component under discussion. However, the degree of separation of the components by starch-block electrophoresis was incomplete as shown in their illustrations. It seems probable that Hb-Alexandra, the foetal form of Hb-Dα St. Louis and our component are identical, but until all three components can be investigated in the same laboratory, a dogmatic assertion is not possible.

The tentative name Hb-Fα D St. Louis is suggested for this foetal haemoglobin in accordance with the nomenclature of abnormal haemoglobins.

IMMUNOLOGY

Formation of Isohaemagglutinins in the Marmoset, *Tamarinus nigricollis*

The small South American primates of the Hapalidae family, the marmosets, are unique in that twin births are an almost consistent occurrence[1]. This twinning phenomenon further is unusual in that all twins appear to be fraternal, and placental vascular anastomoses result in haematopoietic chimerism of the young. Blood chimerism in adult male and female marmosets has been demonstrated by sex-chromosome analyses of cells in metaphase and also by examination of peripheral blood leucocytes for the drumstick-bearing neutrophils[2,3]. Sex-chromosome analysis of lymph node, spleen and bone marrow cells has also revealed chimerism: thus all haematopoietic tissues are involved[3]. Erythrocyte chimerism, although presumed to exist, has not yet been demonstrated owing to the unavailability of blood-grouping reagents in this species. Although previous investigations have indicated the presence of human A- and B-like antigens on the marmoset red cells, differences among marmosets of these human blood group substances are not apparent[4–6]. Tests for naturally occurring isohaemagglutinins in these animals have thus far been negative. The natural blood chimerism assumed to exist in all marmosets because of the twinning phenomenon would appear to preclude or make exceedingly difficult successful red cell isoimmunizations since both donor and recipient could conceivably have two (or more) major genetically distinct blood-group antigens. In a random-bred colony without any breeding records, therefore, the prior knowledge of chimerism in any one animal (as determined by sex-chromosome analysis) could be of considerable value. Thus, if on the basis of sex-chromosome analysis one could find an animal that is definitely a heterosexual chimera, yet in only a small proportion (10–20 per cent), its red cells would be more desirable for immunization purposes in making specific reagents than those of an animal with a relatively high degree of chimerism, or one in which the degree of chimerism is not known. This procedure would have merit only if the degree of chimerism as determined by sex-chromosome analysis of dividing white cells is also representative of the chimerism of the erythropoietic system, an assumption that must be made until evidence shows otherwise. In an analysis of the dividing white cells of the peripheral blood of twenty-six marmosets found to be heterosexual chimeras, two male animals had 12 per cent (No. 21-11-5) and 18 per cent (No. 21-1-1) chimerism of female cells, the lowest observed in our colony. These were then used as red-cell donors for isoimmunizations.

The immunization procedure was as follows: the antigen inoculum for each day consisted of 0·1 ml. unwashed packed red blood cells suspended in 0·1 ml. complete Freund's adjuvant (Difco Laboratories, Detroit, Michigan). Six injections were given on alternate days over a period of 10 days. The first, second and fourth were given intramuscularly in the thigh, the third and fifth subcutaneously in the inguinal area, and the last intraperitoneally. Previous attempts at immunization with Freund's adjuvant injected into the footpad of the hind limbs resulted in deep ulcerations approximately 14–21 days after injection. These invariably led to death of the animals. Slight ulcerations were also observed after intramuscular injections. In the present series, one animal (26-3-2) was removed from the experiment after the third injection for use in our breeding programme and another (23-5-1) was substituted in its place. This animal (26-3-2), however, later (1 month later) developed a severe ulceration on one thigh at the site of the intramuscular injection and was killed to prevent further suffering.

The isoagglutinin responses obtained in five animals at varying intervals after the last injection are indicated in Table 1. Each serum was tested *in vitro* in saline with the specific cells used for immunization and also with the cells of a second marmoset. An excellent agglutinin response was obtained with marmoset 26-5-5 after immunization with red cells from marmoset 21-1-1. This serum also reacted strongly with cells of 21-11-5, although later bleedings showed a faster decline in antibody reactive with these cells than with the immunizing cells. Marmoset 27-4-4 became ill (from an unknown cause) 16 days after the last injection and was killed as death appeared certain. His serum contained agglutinating antibody to the specific immunizing cells only. Marmoset 26-3-2, which was removed from the experiment after only three injections of red cells, also formed specific agglutinins. Of interest was the response of marmoset 21-7-2, which, although immunized with cells of 21-1-1, failed to develop agglutinins reactive with these cells, but instead formed agglutinins reactive with cells of 21-11-5. This development would be difficult to explain except for the blood chimerism of these animals. It is possible that the 18 per cent chimeric portion of red cells of marmoset 21-1-1 has antigenic determinants common with the 88 per cent chimeric portion of the red cells of 21-11-5, and immunization of marmoset 21-7-2 may have been effected through the minor population of red cells present in donor 21-1-1. Consequently, in the *in vitro* test, the antibody formed is

† Animal became ill and was killed by cardiac puncture.
‡ Animal received only three injections of antigen and was killed by cardiac puncture on day 50 after development of severe ulceration at site of intramuscular injection.

evident when tested with cells of marmoset 21-11-5, since the percentage of cells having the specific antigens available for reaction would be greater. The smaller proportion of the specific antigenic cells of 21-1-1 may not have been sufficient to detect any *in vitro* agglutinating activity of the weakly reactive antibody. That there is some common antigenicity between red cells of marmosets 21-1-1 and 21-11-5 was most evident when the reaction of serum 26-5-5 was tested *in vitro* with these cells. A clearer understanding of this interpretation should be forthcoming when the blood-group relationships of the immunized recipients and cell donors become established using reagents that are being developed in this laboratory.

My investigations show that it is feasible to develop isohaemagglutinin reagents in the marmoset, even though blood chimerism exists. The rationale for the experimental immunization procedure, that is, the use of animals known to have a low degree of such chimerism, can now be extended to testing of such immune reagents *in vitro* with red cells of animals also assumed to have a low red-cell chimerism. My present efforts are directed toward such panel testing of cells from our colony of marmosets with the hope of detecting suitable antigenic differences to permit further isoimmunizations. The delineation of blood groups in these animals will subsequently permit the evaluation of the erythrocyte chimerism as well as that of the white cells. Certainly, the haematopoietic chimerism of the marmoset makes it a most interesting laboratory primate for studies in haematology, immunology and radiation effects[7].

Immunoelectrophoretic Examination of Avian Serum Esterases

It has been recognized for some time that immunochemical properties provide a useful criterion for differentiating enzymes. When immunoelectrophoretic analysis was used in investigations of esterases in sera of birds it showed that greater variations occurred in their properties than has been revealed by simple agar electrophoresis[1–3].

Two species were more extensively investigated, namely, duck and quail, and other Gallinaceae were used for comparison; sera of individual birds were analysed after storage at either −12° C or +4° C for from 1 day to 1 year (as the esterases in the plasma were the same as in the sera, the analyses were in some cases performed as early as 1 h after bleeding).

The routine method used, based on that of Uriel[4], involved photographically recording lines of precipitation, usually after 48 h, washing in saline for 6 days, photographing again, and then drying; the esterases were then revealed by a suitable substrate and the result was recorded photographically; for the detection of proteins, the plate could be later stained with amido black. A duplicate plate was stained with Sudan black to detect the lipids present.

Using such techniques the avian sera disclosed several esterases which differed in electrophoretic localization, antigenic specificity, biochemical characteristics, behaviour during storage, and intraspecific variability.

The total number of esterase-active components detectable in a serum depends on the immunoserum (large differences have been found in the number and levels of antibodies produced between identically immunized rabbits) and on the substrate used to reveal enzyme activity (some antigen–antibody complexes preferentially hydrolyse the β-naphthyl acetate or butyrate, others the indoxyl acetate, while in simple agar electrophoresis these substrates appear to be hydrolysed to the same extent).

On the whole, six active components were observed: two β_1-globulins, one α_2- and one α_1-globulins; the remaining two esterases could not be assigned a definite rate of migration, as the localization of one of them varied from sample to sample between α_2- and α_0-regions, and the other from α_1 to a very rapid ρ (Fig. 1).

All these esterases were antigenically independent and this was demonstrated by the crossing of precipitation or activity lines when their electrophoretic localization was sufficiently close (Fig. 2). One of the β_1, the α_2–α_0 and the α_1–ρ esterases are lipoproteins (Fig. 3).

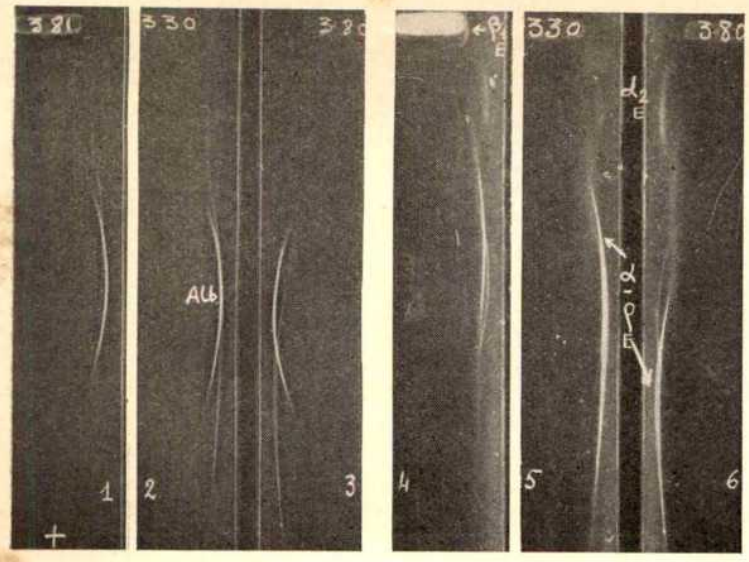

Fig. 1. Precipitation lines (1, 2, 3) and corresponding esterase staining (4, 5, 6) for quail serum. 1 and 4, Fresh sample; 2 and 5, serum stored for 8 days; 3 and 6, serum stored for 1 month

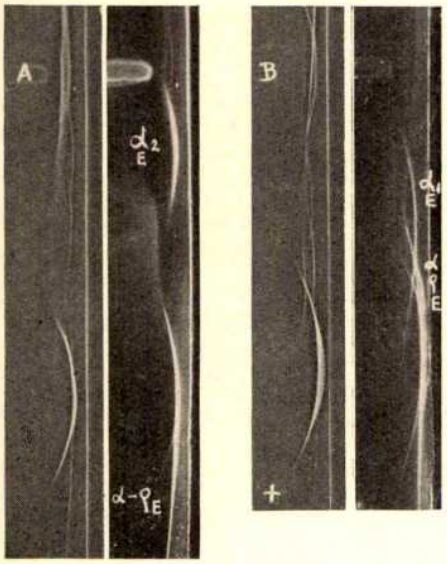

Fig. 2. Precipitation lines and corresponding esterase staining for duck serum. Serum *A* contains the α_2-esterase (note the visible precipitation line); serum *B* shows the α_1-esterase (no corresponding line can be seen) crossing the α–ρ esterase

Changes in the migration rate of the ρ lipoprotein in duck sera have already been reported[1,3,5] to be approximately proportional to the length of time it is kept in storage. The immunoelectrophoretic results confirm these observations and reveal, for fresh samples, an arc in the α_1-position (Fig. 1); in older samples the line is progressively displaced towards the anode and, in sera stored for 1 month, it is definitely faster than albumin (Fig. 1). The line is then long and straight, which indicates that the molecular charges are very heterogeneous; however, the enzymatic and lipidic properties of these samples do not appear to be significantly altered (Fig. 3).

Effects analogous to those autolytic modifications were obtained with various agents: (1) digestion of serum by porcine pancreatic lipase; (2) intravenous injection of heparin to the animal 15 min before bleeding; (3) incubation with sodium taurocholate. The biochemical alterations induced by these agents are not, however, identical, and the acceleration of the migration rate of ρ esterase by lipase or heparin is significantly enhanced by further incubation with taurocholate.

Previous results disclosed differences in the number of esterases present in sera of birds of the same species[2]. The interpretation given to these electrophoretic findings might, however, be incorrect due to the aforementioned differences in the rate of migration of the α–ρ esterase, which in fresh serum samples may mask the 'true' α-esterase or suggest its presence when it is actually absent. For this reason, use of the antigenic characters makes possible a more reliable confirmation of the presence or absence of a given component.

Taking into account the state of the serum analysed, the quality of the immunoserum and the kind of substrate used, the following esterases were found in all sera examined: (1) the non-lipo-β_1; (2) the α_2–α_0 lipo-esterase; (3) the α–ρ lipo-esterase. The three other components seem to be individual features, either as genetically determined factors or as expressions of a physiological or pathological alteration.

The esterase–antibody complexes are generally detected as precipitation lines exhibiting hydrolytic activity towards suitable substrates. With some antisera, however, the precipitation line of α–ρ does not react with the usual substrates[6], or, if it does, only very weakly; this might be due to the presence of neutralizing antibodies. On the other hand, the α_1-esterase is exclusively revealed by incubation with the substrate: its coloured arc could not be attributed to any of the visible precipitation lines nor could it be stained with amido black[5,6] (Fig. 4). One possible explanation of this finding is that the total amount of protein contained in the antigen–antibody complex is too low to form a visible precipitate or even to take up the strain. Attempts to increase this amount or to modify the antigen–antibody proportions have so far been unsuccessful.

The avian serum esterases are, finally, characterized by species-specific antigenic properties similar to other serum proteins: for example, using the anti-quail antiserum, the α–ρ esterase was detected in sera of turkey, chicken, pheasant, guinea-fowl; a weaker reaction was observed with duck and goose sera.

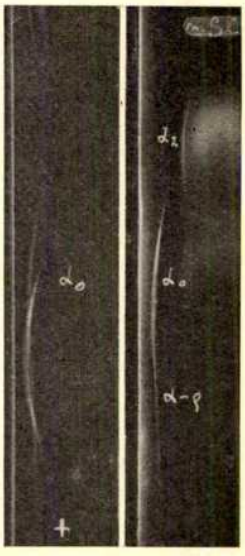

Fig. 3. Precipitation lines and lipid staining for quail serum

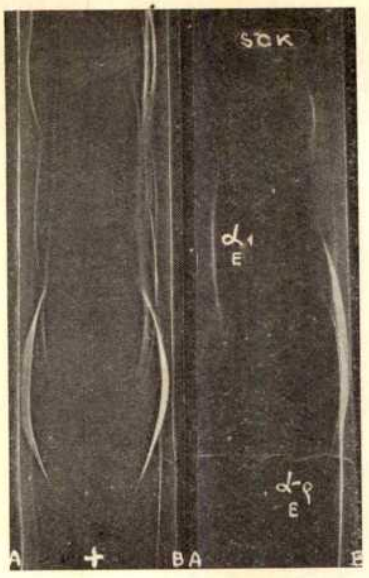

Fig. 4. Comparison of precipitation lines and esterase activity revealed by two immunosera: with *A* the α–ϱ line does not react with the substrate, the α_1 esterase gives a strong reaction; with *B* the α–ϱ line is active but the α_1-esterase is scarcely visible

I thank Mme. M. Jeanne-Rose for her assistance in this work.

Fluorescent Antibodies in the Fluid of the Conjunctival Sac of Trachoma Patients

THE indirect fluorescent antibody technique was used to investigate the possible presence of antibodies in the lacrimal fluid or, to be more exact, the fluid of the conjunctival sac of 21 patients with active trachoma (Stage II–III), nearly all of them children, 9–14 years old. In most instances, the small quantity of fluid normally present in the conjunctival sac, or produced by slight mechanical irritation rather than freely flowing tears, was examined. The fluids, obtained with the aid of sterile pipettes used for white blood-cell count, were diluted 1 : 10 in phosphate buffered saline *p*H 7·4. Trachoma elementary body antigens were prepared and examinations were carried out by techniques previously described[1–3]. Commercial fluorescein isothiocyanate labelled anti-human γ-globulin (Microbiological Associates, Bethesda) and rhodamine were used for the purpose of staining. Fluorescence with trachoma antigen was observed with the conjunctival fluids of ten from the twenty-one cases of trachoma. The conjunctival fluids from twenty-two trachoma-free children gave negative results.

In the positive samples, elementary bodies stood out clearly with a minimum of non-specific background staining.

A number of experiments were carried out to examine if specific antibodies were involved in the reactions. Conjunctival fluids which gave a positive reaction with elementary bodies of trachoma strains failed to react with elementary bodies of psittacosis (6*BC* strain) prepared by the same technique. Heating positive conjunctival fluid for 30 min at 56° C did not abolish fluorescence. After digestion of positive conjunctival fluid with trypsin solution (twice recrystallized, 1 mg/ml. in saline phosphate buffer *p*H 7·4 kept for 150 min at 37° C) fluorescence with trachoma antigen was no longer observed.

The high degree of specificity, thermostability and sensitivity to trypsin observed with positive conjunctival fluids suggests that true antibodies were responsible for the fluorescence reactions.

In sixteen trachoma patients, antibody determinations by the indirect fluorescent method were simultaneously performed in conjunctival fluids and blood serum. Table 1 presents the results for nine positive cases and demonstrates that in some instances antibody titres were higher in the conjunctival fluids than in the serum. Blood and conjunctival fluids were obtained from these patients repeatedly during a 6-week period. Similar antibody titres were observed on each occasion. It was also found that similar antibody titres were present in the conjunctival fluids of both eyes from the same patient.

The relationship of antibodies in the conjunctival fluid to those in the serum remains to be clarified. Flemming and Allison reported that no serum proteins were present in the tears of four healthy individuals[4]. Normally, antibodies in the serum do not seem to pass into the conjunctival fluid. No fluorescent antibodies were observed in the conjunctival fluid of two rabbits hyperimmunized against trachoma and possessing serum antibodies in titres greater than 1 : 10,000, determined by the indirect method. Inflammatory processes may lead, however, to an increased permeability of the capillary walls. Thus, antibodies may appear and possibly become concentrated extravasally at the infected site. The higher titre of antibodies in the conjunctival fluids than in the blood, observed in a number of our cases, may be due to such a mechanism. The possibility of locally produced antibodies must also be considered. Large numbers of lymphocytes and plasma cells are present in the trachoma-infected conjunctiva. These cells, as well as local lymph nodes, might furnish the necessary apparatus for antibody production. It seems less probable that antibodies are produced in the lacrimal glands.

Table 1. FLUORESCENT ANTIBODIES IN CONJUNCTIVAL FLUIDS AND SERA OF TRACHOMA PATIENTS (INDIRECT TEST)

Patient No.	Conjunctival fluid	Serum
1	80	20
2	20	< 5
3	40	5
4	120	40
5	10	40
6	10	< 5
7	10	30
8	30	160
9	20	40

The practical importance of these generally low-titred antibodies in conjunctival fluids of trachoma patients remains to be demonstrated. The chronic character of the disease points to a low efficiency of the immune response. It is also known, however, that the isolation of trachoma agents from the conjunctiva of patients and the demonstration of Halberstaedter-Prowazek inclusion bodies succeed only in the early stages of the disease. The gradual elimination of the agent from the infected tissues may be due to low-titre antibodies present in the conjunctival fluids.

Preliminary results indicate that it is possible to raise the antibody titre in the serum and the conjunctival fluids of some trachoma patients by a single injection of an inactive trachoma vaccine. The effect of optically applied antigen is under investigation. It will also be of interest to examine whether antibodies can be produced in the conjunctival fluids of normal individuals and whether passage of serum antibodies into the conjunctival sac can be elicited by a local inflammatory reaction.

PATHOLOGY

Carcinogenic Activity of *N*-Methyl-*N*-nitroso-*N'*-nitroguanidine

N-Methyl-*N*-nitrosourethane (MNU) (I) and its ethyl homologue have been found to be effective carcinogens, which can induce stomach, oesophageal, intestinal and lung tumours with one or a few doses[1–6]. As urethane itself is carcinogenic it seemed of interest to test the related *N*-alkyl-*N*-nitroso-*N'*-nitroguanidines, in order to assess the role of the ethoxycarbonyl-group in the carcinogenic action.

(I) (II) (III)

The commercially available crystalline compounds, *N*-methyl-*N*-nitroso-*N'*-nitroguanidine (MNG) (II), *N*-ethyl-*N*-nitroso-*N'*-nitroguanidine (ENG), and *N*-methyl-*N'*-nitroguanidine (MG) were tested in rats by intragastric administration. For this purpose, the compounds, which are very sparingly soluble in water or in ethanol, were used as suspensions in 30 per cent aqueous ethanol, and were given by stomach tube to young male and female white rats, weighing 50–100 g. The number of doses varied between 3–5; each represented about 50–100 mg/kg body-weight. The doses were given at several months' intervals and amounted to 10–50 mg per rat *in toto*. The animals tolerated the treatment well; their growth rate did not significantly differ from that of control rats. All the animals were maintained under uniform conditions, and were given food (MRC diet 41*B*) and water *ad libitum*.

So far, four male and four female rats killed between 12 and 24 months after the first dose of MNG had tumours of the fore-stomach. The tumours were mostly multiple; when still small they appeared to have multicentric origin. Some formed narrow, elongated, tongue-like projections into the stomach lumen, others formed nodules containing keratin pearls in the centre. The larger tumours formed co-fluent masses of erupting keratinizing nodules covering the whole squamous part of the stomach and spreading among the muscle bundles of the stomach wall and also under the mucosa of the glandular part. One rat had numerous metastatic nodules in the peritoneal cavity (Figs. 1 and 2). Among these rats no tumours of the glandular stomach were seen, though abnormalities and hyperplasia of the glandular mucosa were present in some. Among the rats killed after similar time and having been given similar doses of *N*-ethyl-*N*-nitroso-*N'*-nitroguanidine and of *N*-methyl-*N'*-nitroguanidine no stomach tumours have as yet been seen.

The finding that *N*-methyl-*N*-nitroso-*N'*-nitroguanidine is an effective carcinogen for the rat fore-stomach provides additional evidence that the carcinogenic activity must be connected with the *N*-alkyl-*N*-nitroso- groups of this class of compound (Magee and Schoental[5]). The ethoxycarbonyl- (in the case of the urethanes, I), the amido (in the case of the very carcinogenic urea compound, III (ref. 6)) and the carbimino-amine group (in the case of guanidine, II) appear to affect the rate of interaction of the respective compounds with cell constituents. *N*-Methyl-*N*-nitroso-*N'*-nitroguanidine (II) is an effective mutagen[7,8], resembling also in this respect *N*-methyl-*N*-nitrosourethane (I) (ref. 5). *In vitro*, MNG (like MNU[9]) interacts with sulphydryl compounds at neutral *p*H, and nitrogen is evolved in the process (Schoental, unpublished results). The relatively low toxicity and lack of necrotizing action of MNG may be related to its low solubility and possibly to a slower rate of its interaction with tissues. Although nitrogen of the *N*-nitroso-group is evolved as gas in this process, it still remains to be shown whether the diazoalkanes or the 'active alkylenes' are the effective agents in the carcinogenic action of the *N*-alkyl-*N*-nitroso compounds.

The induction of squamous carcinomata in the fore-stomach of rats by intragastric administration of MNG provides additional evidence that the carcinogenic action

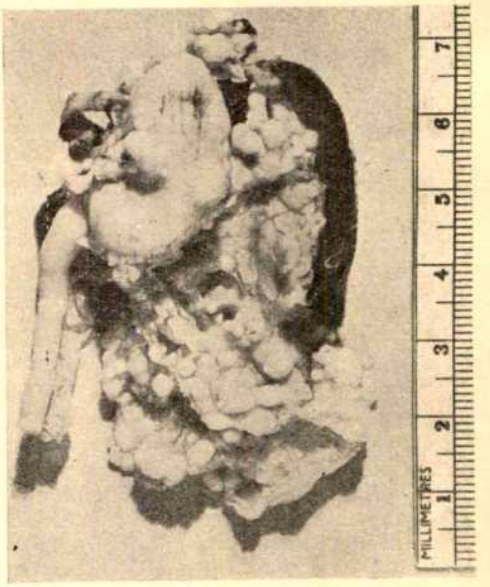

Fig. 1. Stomach of a female rat, killed 15½ months after the first of three doses of MNG (30 mg/rat *in toto*) with numerous metastatic nodules

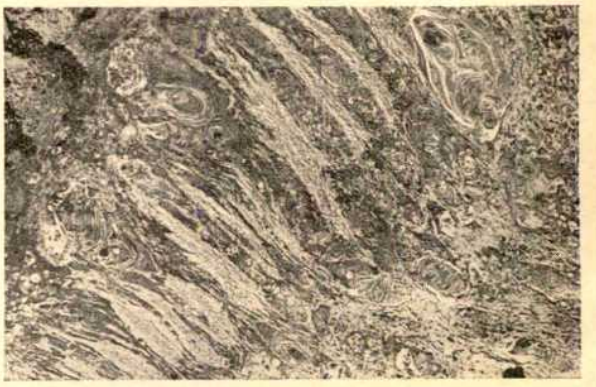

Fig. 2. Squamous carcinoma of stomach found in a female rat, killed 15½ months after the first of three doses of MNG (26 mg/rat *in toto*). (Haematoxylin and eosin, × *c.* 22)

of the *N*-alkyl-*N*-nitroso compounds is related to their alkylnitroso groups.

I thank Mr. I. Caldwell for his technical assistance.

Lactate Dehydrogenase Isoenzymes in Malignant Tissues

PREVIOUS reports from this laboratory have shown that the electrophoretically fast lactate dehydrogenase isoenzymes, LD_1 and LD_2, of human and animal tissues exhibit high activity with 3·3 mM 2-oxobutyrate as substrate relative to that with 0·7 mM pyruvate[1,2].

Values for the ratio, $\text{activity}_{\text{2-oxobutyrate}}/\text{activity}_{\text{pyruvate}}$, approach unity in tissues such as heart muscle in which LD_1 and LD_2 predominate and fall to about 0·3 in skeletal muscle in which LD_4 and LD_5 are the principal isoenzymes. By comparison with those of normal tissues, the proportions of the slow isoenzymes LD_4 and LD_5 in certain malignant tissues have been shown by DEAE-'Sephadex' chromatography[3] and by electrophoresis on agar-gel[4] and cellulose acetate[5] to be increased. We therefore considered it of interest to determine whether such a shift in the isoenzyme pattern occurs in tumours generally and if so whether it is reflected by a change in the $\text{activity}_{\text{2-oxobutyrate}}/\text{activity}_{\text{pyruvate}}$ ratio.

Portions of tumours and of contiguous normal tissues removed at operation or at autopsy were extracted immediately or after storage at −15° overnight. The tissues were homogenized in a Potter–Elvehjem homogenizer in 10 volumes of 0·067 M Sørensen phosphate buffer at *p*H 7·4, and the homogenates were centrifuged at 5,000*g* for 10 min at 0°–5° C. Dehydrogenase activities in the supernatant fractions were then determined spectrophotometrically in a Unicam *SP*500 or a Unicam *SP*800 spectrophotometer at 25° with 0·7 mM pyruvate[6] or 3·3 mM 2-oxobutyrate[1] as substrate and 0·12 mM reduced nicotinamide-adenine dinucleotide as coenzyme.

Lactate dehydrogenase isoenzymes were separated by electrophoresis on either cellulose acetate[7] or in acrylamide-gel[8]. The isoenzymes were located by the MTT tetrazolium staining technique[9], and a quantitative assessment of the relative amounts was made by scanning cellulose acetate electropherograms with a 'Chromoscan' (Joyce, Loebl and Co., Ltd.).

The isoenzyme pattern observed in a lymph node tumour shows a marked shift towards the slow isoenzymes relative to that of a normal lymph node extract (Fig. 1). There is admittedly some doubt concerning the purity of the control specimen, which shows greatest activity at LD_3, but

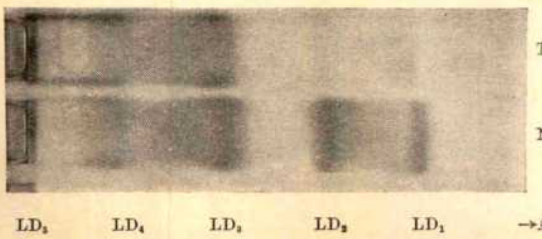

Fig. 1. Lactate dehydrogenase isoenzyme patterns of normal and neoplastic lymph node extracts separated by acrylamide gel electrophoresis

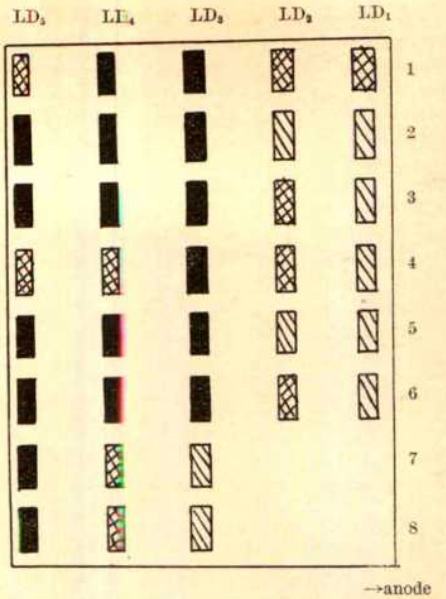

Fig. 2. Diagram of lactate dehydrogenase isoenzyme patterns of normal and neoplastic human tissues and rat tissues separated by acrylamide gel electrophoresis. 1, Normal colon; 2, neoplastic colon; 3, normal colon + neoplastic colon; 4, normal rectum; 5 and 6, rectal tumours; 7, fresh rat tumour; 8, rat tumour 10 days old

the tumour which appeared to be free from contaminating tissues showed most activity in LD_3, LD_4 and LD_5. Similar observations were made with tumours of other tissues, including breast, rectum, colon, stomach, testis and lung. Some of the isoenzyme patterns obtained are illustrated in Fig. 2.

Although visual impressions of the changes in isoenzyme distribution were supported by scanning electropherograms run on cellulose acetate foil, it must be borne in mind that several possible sources of error are inherent in the use of staining techniques. Since isoenzymes differ in their substrate affinities, certain components may function under optimal conditions while others may not be fully saturated or may even be inhibited by excess substrate. Moreover, the more active fractions may utilize all the substrate in their immediate environment and consequently tend to be somewhat under-estimated relative to the weaker fractions.

In an attempt to overcome these objections, $\text{activity}_{\text{2-oxobutyrate}}/\text{activity}_{\text{pyruvate}}$ ratios were determined and the results are given in Table 1. In every case in which it was possible to make a comparison, the tumour showed an activity ratio lower than that of the corresponding normal tissue. The differences are more pronounced when the tumours originate in tissues which normally contain a predominance of fast isoenzymes with relatively high activity ratios, but the changes are apparent even in those tissues normally characterized by moderately low activity ratios.

These quantitative investigations confirm that the shift in the isoenzyme patterns in malignant disease detected by other techniques[2–5] applies to neoplasms generally,

†Dehydrogenase activity determined with 0·7 mM pyruvate as substrate.

but it was necessary to exclude the possibility that the change might be due to the presence of necrotic cells in the tumours. We therefore compared the lactate dehydrogenase isoenzyme patterns and activity ratios of experimental tumours (Walker 256) in the rat 4–5 days after implantation with those observed in a second series of rats 10 days after implantation, by which time the tumours had become necrotic. Similar isoenzyme patterns and similar (low) activity ratios were found in both fresh and necrotic tumours. It seems unlikely, therefore, that the presence of necrotic cells plays an important part in causing the shift in the isoenzyme pattern.

We thank Dr. D. H. Mackenzie and Dr. K. Lewin for the human tissues and Dr. D. Burston for the rat tumours used in this work. The investigation was carried out during the tenure of a World Health Organization fellowship awarded to one of us (H. P.-L.).

Collagenolytic Activity in Gingivae of Man

Recent investigations by Gross *et al.*[1–6] indicate that substantial quantities of collagen are lost from the tail fin of tadpoles during metamorphosis. They have also noted that the back skin, gill and gut, but not muscle, notochord, kidney, gonads, heart, liver and spleen from tadpoles are able to lyse collagen gels when cultured *in vitro*. This collagenolytic activity can be accounted for at least in part by an enzyme active against native collagen which is produced by these tissues[1–6]. Collagenolytic activity has also been reported in the uterus and healing wounds[1].

Since considerable remodelling of periodontal tissues normally occurs, and since large amounts of collagen are lost during the course of periodontal diseases, we have investigated the possibility that these tissues also secrete substances active against native collagen.

More than one hundred specimens of gingivae were obtained from various periodontists who had removed the tissues for the treatment of periodontal diseases. Gingivectomy specimens were placed directly into Tyrode's solution to which had been added 100 u. penicillin/ml., 100 μg streptomycin/ml., and 100 u. 'Mycostatin'/ml. Tissues were shaken briefly, left standing at room temperature for about 30 min, and then placed in another vessel containing Tyrode's solution with antibiotics for a few minutes in order to disperse and remove micro-organisms. Tissues were then removed from the solution, diced into 1–2 mm cubes, and incubated in the Tyrode's solution plus antibiotics either on the surface of a collagen gel or without.

In order to test the ability of the tissues to lyse collagen gels, collagen was prepared from salt and acetic acid extracts of rat skins[7]. In general, collagen gels were prepared according to the method of Gross and Lapiere[2], and Lapiere and Gross[4]. Satisfactory gels were obtained with 0·25 per cent collagen in 0·4 M phosphate buffer. The collagen solutions were poured into 35 or 55 mm plastic Petri dishes to a depth of about 3 mm and incubated at 37° C until firm. The collagen gel was equilibrated with Tyrode's solution with antibiotics for 30 min and drained. Diced tissues were placed on the gel and incubated at 37° for 30 min in a moist chamber to ensure their sticking to the surface of the gel. 1 ml. (55 mm Petri dish) or 0·5 ml. (35 ml. Petri dish) Tyrode's solution with antibiotics was added to the surface of the collagen gels. The cover was sealed with silicone grease to prevent loss of carbon dioxide and resulting *p*H change during the incubation period of 72–96 h.

After 24 h, clearing around gingival tissues (indicating collagenolysis) was generally evident, and clear zones increased with time (Fig. 1). Clearing was not observed around small pieces of rat pancreas, heart, intestine and kidney incubated under comparable conditions for as long as 1 week. Substitution of Eagle's medium with added antibiotic for Tyrode's solution did not appear to affect the extent of lysis[8]. Application of crystalline trypsin to the gels did not produce visible clearing. Collagen gels were readily lysed in the region of 3-mm rings of filter paper soaked in purified collagenase from *Clostridium histolyticum* (0·5 mg/ml. 0·01 M *tris* buffer, *p*H 7·4, containing 10^{-3} calcium ions) and incubated overnight at 37° C.

Collagenolysis could be observed best in stained preparations. Van Gieson's stain and the following procedure are favoured. A few millilitres of 10 per cent formalin are placed on the tissues and the collagen gel for a few hours. The formalin is poured off, and the gels with tissues *in situ* are stained with Van Gieson's mixture (5 ml. 1 per cent acid fuchsin added to 95 ml. saturated picric acid) for a few minutes. The excess stain is rinsed off. Collagen lysis is evident as clear zones. Alternatively, the gels with attached tissues may be stained for a few minutes with an aniline blue solution (0·05 per cent aniline blue in aqueous 0·5 per cent hydrochloric acid) followed by rinsing.

Various observations indicated that cellular activity was required for collagenolytic activity; namely, (*a*) tissues frozen and thawed, and incubation under conditions which otherwise would result in clearing of the gels failed to manifest activity; (*b*) clearing of the gels was not observed in gingival cultures to which puromycin (25 μg/ml.) had been added. Similar observations have been made with tadpole tissues[1–6].

The possibility that bacteria were present in the cultured gingival tissues was examined by placing specimens exhibiting collagenolytic activity into heart-brain infusion and thioglycollate broth. No growth was observed after one week. These and previous investigations carried out by one of us (W. G.) indicate that bacterial contamination does not constitute a problem with gingival cultures prepared in this manner.

In other experiments, excised gingivae were treated with Tyrode's solution with antibiotics, diced into approximately

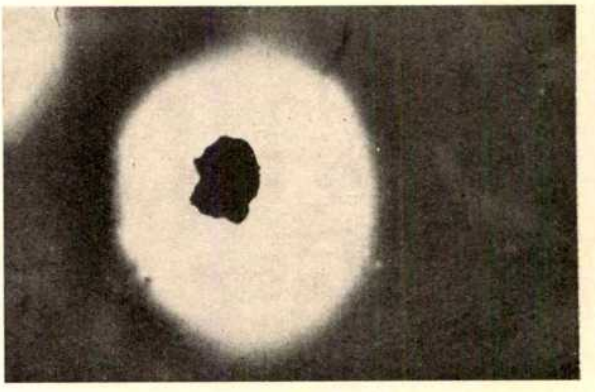

Fig. 1. 72-h gingival culture on a collagen gel afterwards fixed and stained with aniline blue. Note clear zone around incubated tissue indicating collagenolytic activity. Similar tissues frozen and thawed before culture, as well as tissues incubated with puromycin failed to manifest collagenolytic activity

2-mm cubes and cultured for 1 week in 2 ml. Tyrode's solution with antibiotics in sealed 55-mm Petri dishes at 37° C. Tissues were then separated from the culture media by centrifugation at 18,000*g*. The ability of the supernatant to reduce the viscosity of collagen solutions was studied in Ubbelohde viscometers at 20° C in 0·1 M *tris* buffer at *p*H 7·4. Calcium chloride was added to maintain the collagen in solution. Under these conditions, the viscosity of 0·25 per cent collagen solutions was reduced 14–35 per cent as compared with control solutions. This activity was precipitable with 50 per cent ammonium sulphate and largely inactivated by boiling.

These experiments indicate that diseased gingival tissues produce a heat-labile collagenolytic factor when cultured *in vitro*. Inasmuch as large amounts of collagen are lost during the course of periodontal diseases, the contingency that this factor, possibly an enzyme, is concerned with the process is intriguing.

ANATOMY

Double Central Canal in Spinal Cord of Rat

WHILE studying the morphology of thiamine pyrophosphatase (TPPase)-positive Golgi complex in the central nervous system, it was observed that two central canals (Figs. 1 and 2) were present in the mid-thoracic region of the rat spinal cord.

Frozen cryostat sections, 10μ thick, were post-fixed in 10 per cent formalin. The central canal was in the normal position (Fig. 1). The second canal was observed a short distance in front of the grey commissure in the midline in the anterior white commissure (Figs. 1 and 2). This second canal was elongated anteroposterially similarly to the central canal at the same level (Fig. 2), and the canals were of equal length (anteroposteriorly).

When we observed some of the sections of the spinal cord above this level, it appeared at first that the central canal was greatly lengthened in an anteroposterior direction. Then we observed the separation of this lengthened canal into two parts within the grey commissure itself. Observations of additional sections in the same region revealed that the anterior segment of the separated canal gradually extended farther and farther from the central canal and was finally to be seen in the anterior white commissure. Thus the second anterior central canal originally observed in the anterior white commissure was derived from the central canal and was directly continuous with it.

The caudal part of the spinal cord was discarded before this double canal was seen and, for that reason, we do not know how it terminated—whether blindly or by rejoining the central canal. There are numerous reports of the occurrence in human beings of a double spinal cord with a central canal in each division[1], usually in association with various anomalies in the vertebral column, and with signs and symptoms of nervous system involvement. But there is no report of a double spinal canal in a normal spinal cord. The animal described in this report did not have a double spinal cord and the vertebral column was normal; there were no signs and symptoms of nervous system involvement. It would be of interest to know if similar double central canals are found in other species of animals, including man, and how commonly they occur.

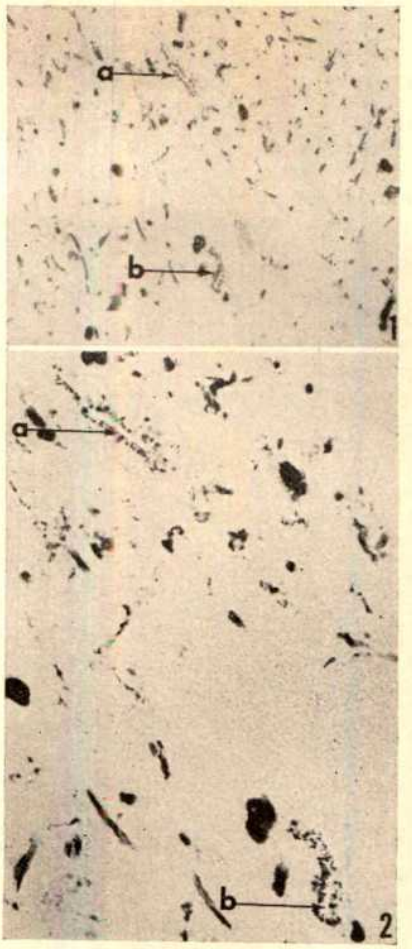

Fig. 1. Low-power photomicrograph of the spinal cord of the rat showing two central canals. One central canal (*a*) is found in the centre of the grey matter as observed in normal spinal cords. The second central canal (*b*) is found in the anterior white commissure. Note that both these canals are placed in the midline. (×*c*. 100)

Fig. 2. Higher magnification of Fig. 1 showing double central canal (*a*, *b*) more clearly. Both figures are thiamine pyrophosphatase (TPPase) preparations. Note the TPPase-positive Golgi material found at the apical borders of the ependymal cells surrounding the lumen (×*c*. 250)

It is interesting that the ependymal lining of both these central canals were cytologically similar. They had discrete granular, vesicular, and comma-shaped TPPase-positive Golgi complex, supranuclear in position. Further details on the TPPase-positive Golgi complex of the ependymal lining as compared with the choroid plexus and ciliary process will be published elsewhere[2–4].

RADIOBIOLOGY

Factors influencing the Staining of Histones in Irradiated Rat Thymocytes

THE most striking cytological event which accompanies the death of thymic lymphocytes is the complete loss of nuclear structure (pycnosis), as seen in fixed and stained preparations or in unstained cells with phase contrast optics[1–3]. Irradiation strongly accelerates this phenomenon and structurally homogeneous nuclei begin to accumulate in thymocyte cultures between 0·5 and 1·0 h after irradiation with doses between 500 and 1,500 r. According to Whitfield *et al.*[1,2], the loss of nuclear structure is accompanied by marked changes in the localization and extractability of histones with hot trichloroacetic acid (TCA). The histones, which are normally localized in the condensed chromatin aggregates of the healthy interphase nucleus, come to be evenly distributed throughout the damaged nucleus while some escape into the cytoplasm. The histones which do remain in the nucleus become abnormally extractable with hot TCA.

Other workers[4,5] have not observed the presence of histones in the cytoplasms of either irradiated or unirradiated cells containing pycnotic nuclei. In the present communication we will show that this discrepancy is mainly due to differences in the methods of mounting stained cells for microscopic examination.

The detailed method of preparing suspensions of thymocytes from the thymus glands of 27-day-old Sprague–Dawley rats has already been described[1]. The suspensions were irradiated at 37° C with 1,500 r. of 300-kV X-rays from a Seifert 'Isovolt' X-ray machine operating at 10 m.amp. The dose was delivered at a rate of 135 r. per min. The details of the irradiation procedure have been given previously[1]. After irradiation, the cultures (contained in 25 × 150 mm tubes) were rotated about their long axes at 40 r.p.m. in an incubator at 37° C.

The media used were medium 199 (Burroughs Wellcome) and a serum–salts medium. The serum-salts medium was similar to that used by Whitfield and Rixon[3] and consisted of 50 per cent foetal calf serum and 50 per cent Krebs–Ringer solution. The *p*H of cultures in both media was maintained at 7·2 by flushing their gas phases with a mixture of 10 per cent carbon dioxide and 90 per cent air.

The optimal fixation procedure for thymocytes consisted of placing a few drops of suspension on a slide, mixing them with a drop of foetal calf serum and then drying the resulting film in a current of air heated to 37° C. The dried films were then fixed in 10 per cent neutral formalin for at least 30 min. The histones were stained by first extracting the nucleic acids from the cells with hot (100° C) 5 per cent TCA and staining in a 0·1 per cent aqueous solution of fast green FCF at *p*H 8·2 for 1 min (ref. 6). The stained preparations were then either dehydrated with alcohol and xylol and mounted in Canada balsam or they were directly mounted in the water mounting medium 'Aquamount' (made by Edward Gurr, London). Cytoplasmic histones were specifically demonstrated by incubating formalin-fixed cells for 1 h at 37° C in distilled water at *p*H 6·0 containing 300 μg of crystalline ribonuclease (Nutritional Biochemicals Corp., Cleveland, Ohio) per ml. This was followed by staining in 0·1 per cent fast green (*p*H 8·2) for 1 min and mounting in 'Aquamount'.

The reason for using hot TCA in the fast green technique is to remove the nucleic acids to which the histones are bound. Once the nucleic acids are removed, the reactive groups of the histones can then be stained with alkaline fast green. The enzyme ribonuclease should act in the same way to unmask any histones which escape from the nucleus and become bound to the cytoplasmic RNA. We have found this to be true; extraction of the formalin-fixed damaged cells with RN-Aase followed by staining with alkaline fast green and mounting in 'Aquamount' produced the same green-stained crescentic forms as did TCA-fast green procedure (Fig. 1*B*). This observation strongly supported our previous conclusion that a considerable fraction of the histones leave the radiation-damaged nucleus, enter the cytoplasm and there combine with RNA[1,2].

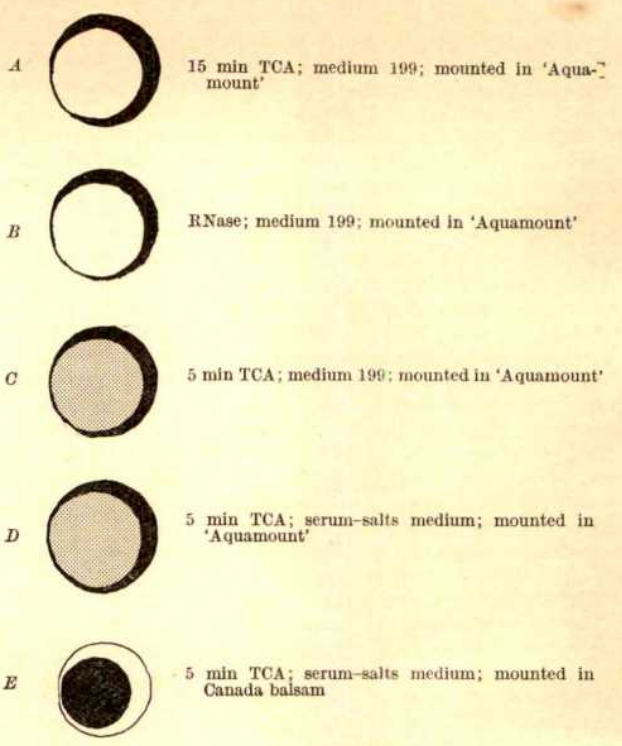

Fig. 1. Diagrammatic representations of the localization of histones in the X-irradiated rat thymocyte which has lost its nuclear structure. The effect of different mounting procedures on the cell size and histone localization can be seen. The histones were stained with alkaline fast-green (ref. 6)

When irradiated thymocytes cultivated in medium 199 were fixed in neutral formalin, extracted for 15 min with TCA and stained with fast green (at *p*H 8·2), the damaged cells with structurally homogeneous (pycnotic) nuclei always appeared as heavily stained green crescents. The homogeneous nuclei of these cells were totally unstained and the stained crescents were found to be the crescentic cytoplasmic masses which surrounded the eccentrically located nuclei[1] (Fig. 1*A*). These observations were invariably obtained with stained preparations which were mounted in 'Aquamount'. If the same stained preparations were then dehydrated with alcohol and xylol and re-mounted in Canada balsam, the cytoplasmic stain was totally extracted and the cells were shrunken. Examination of stained preparations before and after mounting in 'Aquamount' showed that this procedure caused no changes whatsoever in the histone localization of apparent cell size.

The histones in cells (both normal and damaged) cultivated in the serum–salts medium used by Rixon[5] and Whitfield and Rixon[3] were much more easily extracted by hot TCA than those in cells cultivated in medium 199. Extraction of such cells (again both normal and damaged) with TCA for 15 min rendered them totally unstainable. It was necessary to reduce the extraction time with TCA from 15 to 5 min in order to stain the cells. When such cells (extracted with TCA for 5 min) were stained and mounted in 'Aquamount', the homogeneous nuclei of the damaged cells were lightly but diffusely stained with fast green while their cytoplasms were intensely stained (Fig. 1*D*). This picture was identical to that obtained with cells cultivated in medium 199, extracted with TCA

for 5 min and mounted in 'Aquamount' (Fig. 1*C*). When these stained preparations were then dehydrated and remounted in Canada balsam, the cell diameter was reduced, the cytoplasmic stain had been totally extracted and the shrunken nucleus was intensely stained (Fig. 1*E*). This picture of the damaged cell agreed exactly with the one described by Rixon[5] and with the structure of pycnotic follicle cells of the guinea-pig described by Alfert[4].

We conclude from these observations that the optimal procedure for investigating the histone changes in radiation-damaged cells with the fast-green technique of Alfert and Geschwind[6] requires that the stained cells be mounted in a water-mounting medium such as 'Aquamount' and that dehydration with alcohol and xylol be avoided. Dehydration causes severe shrinkage of the cell and it extracts the stain from the cytoplasm. The water-soluble mounting medium, 'Aquamount', does not change the cell size or the degree of staining of any part of the cell. The shrinkage of the nucleus by dehydration is largely responsible for the impression that pycnotic nuclei are severely condensed and hence heavily stained; in reality they are not severely condensed.

Dehydration, after staining with alkaline fast-green, of other types of mammalian cells also extracts the stain from cytoplasmic structures containing basic proteins. Preliminary observations on the localization of basic proteins in fixed and stained normal *L* strain mouse fibroblasts have shown that the cytoplasmic basic proteins located in perinuclear fibrillar structures can be strongly stained with alkaline fast-green provided the stained cells are mounted in 'Aquamount'. However, if the stained cells be dehydrated with alcohol and xylol and mounted in Canada balsam, only the nuclei are stained while their cytoplasms are completely unstained.

BIOLOGY

'Erythroblastosis Foetalis' in the Primate, *Tamarinus nigricollis*

Foetal and neonatal haemolytic anaemia, erythroblastosis foetalis, occurs naturally in man and is a major cause of human intrauterine and *post partum* death. However, it occurs spontaneously in few other species; in the equines especially after cross-breeding between horses and donkeys, and in some pigs after anti-viral immunizations[1]. It has been experimentally produced in dogs and rabbits by isoimmunization with paternal erythrocytes[1]. To our knowledge it has not previously been reported as occurring naturally or experimentally in primates other than man. The present report offers both histopathological and serological evidence suggesting isoimmunization during pregnancy in the primate, *Tamarinus nigricollis*, a New World monkey of the marmoset family.

Although this marmoset has been successfully bred in our laboratory, many pregnancies have terminated in spontaneous abortion, stillbirths and premature deliveries. These misfortunes had been attributed entirely to unknown inadequacies of the laboratory environment until after a recent delivery of a stillborn foetus and its twin that lived for 16 days. Pathological examination suggested that a disease similar to erythroblastosis foetalis was present in both. Similar histological evidence of the disease was also obtained in twins that died near term *in utero* after the traumatic death of their mother. Unlike the disease in man[2], foetal hydrops and icterus neonatorum were not evident but severe hepatic haemosiderosis was present, as shown by positive Prussian blue staining of the hepatic parenchyma (Fig. 1*A*). Although small foci of extramedullary erythropoiesis are not uncommon in late embryonic and foetal life, these animals showed many enormous erythroblastic islands in distended hepatic sinuses (Fig. 1*B*) and dilated blood vessels of the placental trabeculae (Fig. 1*C*). The placentae of single-born young that have survived do not show these foci (Fig. 1*D*). The young with the disease show smaller erythroblastic foci in the adrenal glands, myocardium and lungs. The bone marrow did not show generalized erythropoietic hyperplasia, but focal areas were seen. The fact that the pulmonary capillaries of the marmoset are not as rich in erythroblasts as are those of the human with erythroblastosis may be due to the more effective filtration of the blood by the double placental circulation shared by these chimeric twins[3]. As in the human disease few other organs show any effects, there being typically only parenchymal hepatic atrophy, and lymphoid degeneration and atrophy in the spleen, thymus and lymph nodes.

Independent serological investigations in both deliveries served to substantiate the pathological interpretation of haemolytic disease in these animals. Thus, in the first case, following the death of the second twin, the serum of the mother was tested for antibody to the paternal cells. As shown in Table 1, both saline and Coombs reactive antibodies were found, the latter having a $\log_2$ titre of 9. In the second case, the cells of both foetuses showed a Coombs positive reaction on direct test, one showing a definite 1 + agglutination, the other a 2 + reaction. The maternal serum also yielded a positive Coombs reaction when tested with the paternal cells. This agglutination, however, as shown in Table 1, was only weakly positive (1 +) over a series of serum dilutions. In view of the blood chimerism known to exist in these

* Detected by Coombs test with rabbit-anti-marmoset immune serum.

animals, this finding may be interpreted as being due to the existence of two genetically different populations of red cells in the father, only one of which is reacting with the maternal antibody. This interpretation may also apply to the reactions observed with the direct Coombs test of the foetal cells noted here.

The present studies also indicate the existence of strong antigenic blood group differences in the marmoset, confirming an earlier report by Gengozian on successful isoimmunizations in these animals[4]. Whether the blood group antigen(s) responsible for the haemolytic disease of the new-born is similar or related to the Rh–Hr system of humans[5] is not known, although previous attempts to detect such factors on marmoset red cells have failed. Only the presence of human A- and B-like antigens on their cells has been established thus far[6–8]. In any event, the delineation of isoimmunization during pregnancy in these animals indicates antigenic determinants on their red cells capable of reacting in a manner analogous to the Rh_0 factor of humans. As in humans, the transmission of maternal antibody to the foetus occurs *in utero*, although a significant effect may be exerted through the colostrum following birth. This role of colostrum is suggested by the death of the infant 16 days *post partum*, where pathological findings suggest that the severe haemolytic process in this animal continued after birth (Fig. 1*A*).

The natural occurrence of haemolytic disease of the new-born in this species is of particular interest in view of the nature of twinning among these primates. Thus, the marmosets are unique in that (*a*) fraternal twin births are an almost consistent occurrence[3,9], and (*b*) placental vascular anastomoses result in foetal haematopoietic chimerism[10,11]. The trabecular rather than villous structure of these placentae also affords many areas of intimate contact of maternal and foetal tissues that could potentiate isoimmunization of the mother. This anatomical structure combined with consistent fraternal twinning and blood chimerism would seem to improve the chances of this disease occurring naturally. This primate, therefore, would appear to offer many experimental approaches to the study of the prevention and cure of this disease. Also, one obvious way to promote a successful breeding programme would be the selection of suitable male–female pairings for mating, and we are presently attempting this.

This investigation was supported by U.S. Public Health Service Research grant *R* 01 *AM*09289–01 *AIB*, from the National Institutes of Health.

Specificity of Male Sex Attractants in some Australian Scorpion Flies

Species of the Australian genus *Harpobittacus* (Bittacidae, Mecoptera) have a complex mating habit not recorded elsewhere in the Insecta (Bornemissza[1]). It involves the release of a sex pheromone by two intertergal vesicles on the abdomen of the males which lures females to its vicinity. Mating follows, during which the male presents to the female a nuptial meal consisting of a previously captured insect[2]. Of the six known species of *Harpobittacus*, the mating behaviour of four has been investigated and found to be essentially identical.

Species of *Harpobittacus* (in contrast with those of the world-wide *Bittacus* (see Setty[3])) are allopatric in distribution. Both they and their sub-species are readily distinguishable although, rather surprisingly, difficulty arises with the females of *H. similis* E.-P., which is restricted to an area within 100 miles of Perth, Western Australia, and of *H. australis* (Klug), occurring only in the eastern States. Riek[4] considers, on morphological grounds, that these two taxa may be only sub-specifically distinct. In view of the probability that the western shield has been isolated from the eastern part of this continent since the Middle Cretaceous[5], it was of interest to determine whether the two populations had become reproductively isolated also. The investigation was broadened by the inclusion in the tests of a coastal species from New South Wales, *H. tillyardi* E.-P.

Two types of laboratory experiments were conducted: (*a*) For each sex of each species, small numbers were housed in rectangular gauze cages. Pairs of such cages were arranged so that the airflow from an electric fan passed first through one containing males, and then through one containing females; the reaction of the latter to the male pheromone was recorded. (*b*) Different sex pair combinations of the three species were placed in transparent cylindrical containers closed with nylon mesh, and their behaviour noted.

In all cases, caged females responded to the pheromone emanating only from the males of the same species by congregating on the side of the cage nearest to them.

Caged pairs of the same species mated normally, but when pairs consisting of different species were confined attempts at mating rarely occurred. Mating attempts (which never resulted in impregnation of the female) occurred only when the female present was *H. australis*, and then only in one of fifteen replicates of male *H. similis* and in one of ten replicates of male *H. tillyardi*.

In the field, free-flying *H. australis* females responded to caged males of the same species 10 metres distant, but ignored cages containing *H. tillyardi*.

These results indicate a high order of specificity of the sex pheromones (although to the human sense all three have a uniform butyric-musty odour), and suggest that *H. australis* and *H. similis* are valid species, exhibiting both geographical and reproductive isolation.

Despite the lack of overt reaction by unmated females to the pheromones of other species, the males appear to be highly sensitive to them. When caged pairs were exposed to the pheromone of a second species, production of pheromone and even mating by the former ceased abruptly. Due to the allopatry of *Harpobittacus* spp., interference under field conditions could not arise.

The males of *Bittacus*, according to illustrations by Setty[3] and Tjeder[6], have apparently similar intertergal vesicles. It is reasonable to assume that these vesicles produce sex pheromones similar to those of *Harpobittacus*. It would therefore be of considerable interest to investigate the phenomena of sex attraction and mating in dense sympatric populations of *Bittacus* spp., such as occur in North America (Setty[3]).

I thank Dr. D. H. Edward, Zoology Department, University of Western Australia, for the generous supply of *H. similis*.

Temperature Optima for Algal Development in Yellowstone and Iceland Hot Springs

In analysing the influence of specific environmental factors on growth, it is desirable to study habitats where only a single factor varies. Hot springs provide suitable habitats where temperature is the only variable, so that the relation of temperature to biological development can be measured directly.

Yellowstone National Park has probably the largest number of thermal features for a comparable area of any region in the world. The numerous springs and hot pools have been well characterized in the classic monograph of Allen and Day[1]. In general, the hot springs are concentrated in basins, each often containing numerous thermal features differing in size, temperature, chemical characteristics and water flow. Although some springs are highly variable, others are remarkably constant in thermal, chemical and hydrological properties. Indeed, we have found the thermal characteristics of some springs studied by Allen and Day in the 'twenties to be unchanged in 1965, and there is good reason to believe that they have essentially remained constant for many centuries. Thermal activity at Yellowstone is thought to pre-date the last glacial age[1].

The Yellowstone springs vary in chemical composition, and three types have been recognized: alkaline springs, acid springs, and travertine-depositing springs which are high in calcium carbonate. These three types of springs also differ considerably in biological characteristics. We have concentrated our work primarily on the alkaline springs because these are the most numerous, exhibit the greatest biological development, and because they yield the largest amounts of water. Most alkaline springs of any antiquity have built up large cones composed primarily of siliceous sinter: these deposits are laterally flat and have a remarkably gentle and uniform longitudinal physical descent from the source. Source water overflows and descends across the sinter cone in one or a few narrow channels or in broad sheets of water, cooling as it flows, and in a favourable situation one can find a constant and uniform thermal gradient from a temperature in the high 80's or low 90's down to 25°–30° C. Along this thermal gradient, blue-green algae proliferate, and much of the attractive colour of Yellowstone springs is due to these organisms (bacteria are also present, but, by microscopic observation, it is estimated that they comprise less than 5 per cent of the total biomass). Thermal activity usually prevents terrestrial vegetation near the springs so that there is no shading, and organisms along the thermal gradient are equally exposed to light. It is not difficult to find pools where the water of the overflow is derived from a single source, so that the initial chemical composition of the water flowing over all the organisms along the thermal gradient is identical.

Although we have made casual observations in many regions of the Park, the quantitative investigations reported here were performed on Firehole Pool and two unnamed springs located along the Firehole Lake Loop Road in the Lower Geyser Basin. The extent of algal development in any spring is strongly influenced by the amount and rate of water flow, and since the springs differed in this factor, they also differed in algal content, but all exhibited similar thermal gradients. To eliminate flow rate as a variable all samples from a single outflow were taken as nearly as possible from areas which had the same amount and rate of water flow. Temperature was measured either with a conventional mercury thermometer or with a Yellow Springs Instrument Co. model 42 thermistor. Duplicate samples of the algal mat and underlying siliceous sinter were taken with a brass coring device 2·27 cm² in area. Preliminary experiments showed that essentially all the chlorophyll-containing material was above the sinter, even where very loose sinter was encountered; therefore a core depth of 1–2 cm, which included 0·5 cm or more of underlying sinter, was routinely used. One sample at each temperature was placed in a 15 ml. polypropylene tube and within an hour was covered with 3 ml. of acetone. Within 12 h these cores were homogenized in the tubes with a 'Teflon' homogenizer. The tubes were centrifuged at 5,000 r.p.m. for 5 min and the pellets treated once or twice more with acetone until all the chlorophyll was extracted and the siliceous sinter (which was an excellent abrasive) had been converted to a fine powder. All the extracts from a core were combined, the volume determined, and the chlorophyll content estimated by reading the optical density at 665 mμ with a Bausch and Lomb 'Spectronic 20' colorimeter. (In all cases, it was ascertained by reading at other wave-lengths that the peak absorption was at 665 mμ.) Chlorophyll *A* was estimated from the optical density readings with the relationships given by Odum *et al.*[2].

The pellet from the acetone extraction was then treated with 5 ml. of 0·5 N perchloric acid at 90° C for 20 min, centrifuged, and the supernatant retained for RNA assay using the orcinol[3] method. DNA could not be assayed because of some material interfering with the diphenylamine colour reaction. The pellet was suspended in 5 ml. of 1 N sodium hydroxide and heated at 90° C for 20 min. After centrifugation, this supernatant was assayed for protein by the method of Lowry *et al.*[4] using crystalline lysozyme as a standard. Control samples of sinter, taken from water at 93° C and free of living organisms (by microscopic observation), were treated in the foregoing manner and these gave essentially no colorimetric readings, showing that the assays of experimental samples had biological meaning. The other sample at each temperature was preserved in 4 per cent formalin and assayed several weeks later in the laboratory, using the procedures already outlined. In general, there was good agreement between the values for the duplicate samples, and only the data for the samples extracted directly into acetone are given.

Fig. 1 shows the relationship between temperature of sample and biochemical content per unit area for one of the springs. In general, there was a good correlation among the contents of chlorophyll, nucleic acid and protein for each sample. Each curve exhibits a characteristic sharp optimum at a temperature of 54° C. A sharp temperature optimum in another spring (Firehole Pool) was found at 51° C, whereas in the small unnamed spring just east of Pink Cone Geyser, the optimum was 56° C. The three springs differed considerably in the maximum amount of algal development, probably due to differences in flow rate, but in each case the temperature optimum was quite similar. Microscopic investigations showed that the number and composition of species changed as one moved down the gradient, as has also been observed by others[5], but these changes are of no consequence in our investigations, since we assume that the organisms found at a given temperature are those best adapted to that temperature.

Pure Chemistry Library,
SCIENCE COLLEGE

The fact that the optimum temperature for algal development in these alkaline springs is 51°–56° C can be readily verified by mere visual inspection in a variety of springs where quantitative sampling is not feasible, since the marked algal growth in this temperature range leads to the appearance of the brilliant colours so characteristic of these alkaline springs. (The bulk of the colour seen is not chlorophyll, however, but an orange pigment which has an absorption peak about 450 mμ.) Indeed, even the casual tourist, armed with a thermometer, can verify the optimum shown by our quantitative data.

Hot springs are found in large numbers in only two other areas, Iceland and New Zealand. We have made preliminary investigations in Iceland which essentially confirm the Yellowstone results. The geology of hot springs in Iceland has been described in detail by Barth[6]. Hot springs are much more scattered in Iceland than in Yellowstone and are in general less accessible, so that it has not been possible to find many springs which provide complete thermal gradients. We have performed quantitative studies on only one spring in the Geyser group, and the results are shown in Fig. 2. In this spring sharp optimal temperatures for chlorophyll, protein and RNA were found at 48° C. These optima are slightly lower than those found in Yellowstone, but the maximum temperature for growth is also lower, about 60° C. The *p*H of this spring, 9·1, is higher than those of the Yellowstone springs, and this may account for the lower maximum and optimum temperatures. We have also investigated an acid spring at Yellowstone (Roaring Mountain, *p*H 2·2) which visually shows an optimum temperature of about 45° C; however, the algal development in this spring is so sparse that we were not able to perform quantitative assays. Clearly, the temperature optimum will differ in various environments and may be influenced by such other factors as light, nutrient supply, hydrostatic pressure or *p*H.

Probably the most noteworthy aspect of these results is the fact that in all cases the optimum temperature is so high. The factors limiting photosynthetic efficiency have been discussed by Daniels[7], and he points out that in terrestrial environment the concentration of carbon dioxide is usually the limiting factor, rather than light. If the concentration of carbon dioxide is raised so that it is not limiting, then "the bottleneck in increased photosynthesis is the rate of using the photochemical products in the later thermal reactions"[7]. In the alkaline hot springs, where neither light nor carbon dioxide would be expected to be limiting, it seems likely that temperature

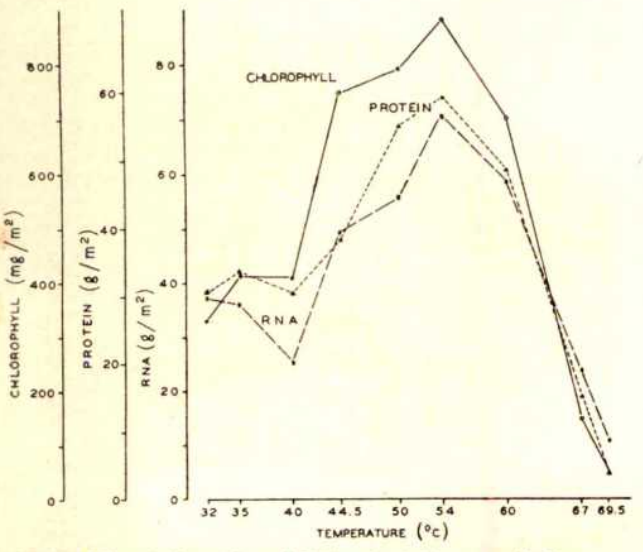

Fig. 1. Chlorophyll, protein, and RNA content of core samples from a large spring in Yellowstone National Park, located on a hillside east of and across the road from White Dome Geyser. Source temperature 72° C, *p*H 8·4

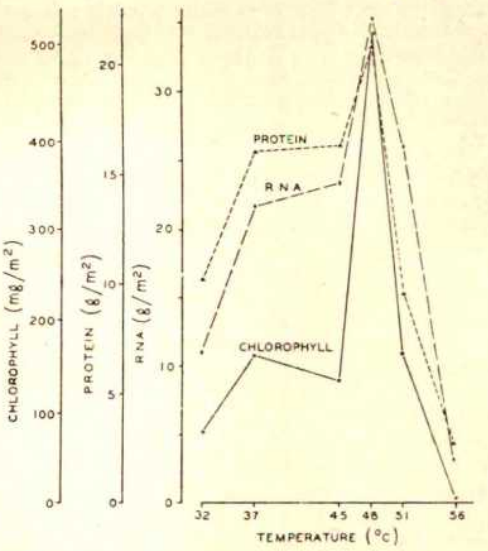

Fig. 2. Chlorophyll, protein, and RNA content of core samples from an Icelandic spring in the Geyser group, near Sisjothandi (Barth's No. 51). Source temperature 92·3° C, *p*H 9·1

is the limiting factor for photosynthetic growth. Only when the temperature reaches values so high that it is probably affecting protein stability or the stability of enzyme-substrate complexes is a further decrease in biological development seen.

The senior author (T. D. B.) is a research career development awardee of the U.S. Public Health Service (grant *AI–K3*–18, 403). The work on Iceland was supported by a grant from the Surtsey-Iceland Research Committee, as administered by Duke University. We thank Pat Holleman for her assistance in this work and Dr. John Wright for providing space in his field laboratory at West Yellowstone. We also thank Mr. John Good, chief naturalist, and the U.S. National Park Service for granting permission to sample in Yellowstone hot springs.

Autoradiography as a Tool in Microbial Ecology

The importance of micro-organisms as agents of biochemical transformations in natural environments is well established. But micro-organisms are small and thus their environments are also small, so that micro-organisms can be investigated directly in Nature only by the use of the microscope. Although the microscope can be used to see where various organisms are situated in a micro-environment and how organisms are disposed with relation to one another, one cannot, however, study microscopically many of the characteristics of an organism which are of greatest ecological interest: that is to say, nutritional requirements, responses to environmental changes, production of metabolites and growth rate. The usual approach

for the study of these latter phenomena has been to isolate micro-organisms in pure culture and attempt to infer from the behaviour of the pure culture the behaviour of the parent organism in Nature. However, it is clear that the behaviour of the pure culture reveals the potentiality of the organism in Nature, but does not show what the organism was actually doing, since the organism has undoubtedly adapted to the cultural conditions used. Further, even if the laboratory conditions precisely mimic the natural conditions, the laboratory environment cannot reproduce the natural environment, since the natural environment contains the additional elements of competition and co-operation with other organisms.

The technique of microscopic autoradiography presented here rectifies in part some of these difficulties, and enables the investigator to obtain some idea directly in Nature of the growth and function of micro-organisms. The technique makes use of the fact that if a micro-organism has assimilated into its protoplasm a radioactive substance with which it is supplied, the presence of this radioactive substance within the microbial cell can be ascertained. The main limitation of this technique is that it must be possible to recognize microscopically in some ecologically relevant way the organisms of interest. After the organisms have assimilated the radioactive material, they are fixed in some way which does not make them morphologically unrecognizable, and they are then affixed to microscope slides. In certain cases, histological procedures may first be needed to make the preparation suitable for microscopy. For example, a plant part or soil sample might be embedded and sectioned. The prepared slides are then dipped in liquid photographic emulsion. (We have used Eastman Kodak '*NTB*-2' nuclear track emulsion, but others may be more desirable for certain purposes, and Prescott[1] should be consulted for details.) After a suitable exposure, which depends on the amount and specific radioactivity of the substance supplied, the extent of radioactivity of the organisms, the nature of the isotope, the thickness of the specimen, etc., the slides are developed and examined phase microscopically. (We have found that a very convenient lens for this examination is the Carl Zeiss Water-Immersion lens, normal aperture 0·75, which can be used directly in a drop of water without a cover slip.) Both radioactive and non-radioactive micro-organisms can be identified, the former being distinguished by the silver grains which appear adjacent to or on top of them. To obtain the best morphological definition, it is essential that the number of silver grains per unit area of organism is not so great as to obscure completely the cell. With a micro-organism of sufficient size, it is often possible to see that one portion of the organism is radioactive, whereas an adjacent portion is not, indicating a functional differentiation within a cell or filament. If fixatives are used, it is probable that radioactivity not present in macromolecules is lost, but in the usual situation the material lost is probably a minor proportion of the total, and can be ignored. Techniques are available for visualizing the radioactivity which is present in a cell in soluble form[2] if required.

This technique can be used in a wide variety of ways to answer a wide variety of questions, and this communication briefly mentions several of them.

For example, in the usual oceanographic or limnological investigation of primary productivity, the photosynthetic fixation of carbon dioxide by aquatic algae is studied by supplying $^{14}CO_2$ to the mixed natural population, and after a given time period the whole population is removed from the water and its radioactivity determined. In this way it is not possible to determine which organisms in the mixed population were actively photosynthesizing at the time of examination. But this question could be answered if a sample of this incubation mixture were examined autoradiographically.

The assimilation by micro-organisms of any other compound available in radioactive form, such as a nutrient or a pesticide, could also be investigated. It should be emphasized that the radioactive compound will be diluted with non-radioactive molecules of the same substance which might be present in the environment, so that it is essential to know the actual specific radioactivity of the compound in the environment before any quantitative significance can be attached to the result. The rate of incorporation of the radioactive material can be estimated by preparing a series of parallel samples incubated for various times. We have used this technique to measure the assimilation of ^{14}C-glutamate by bacteria epiphytic on marine algae, and a representative photograph is shown in Fig. 1. Carbon-14 β-rays have too much energy for high-resolution work, and consequently the morphology of an organism is masked, but the localization of regions of microbial colonization is made easier. For example, the dark area at the axillary region represents a micro-colony of bacteria, while the linear band of silver grains seen in the adjacent area derives from a filament of *Leucothrix mucor*. This picture illustrates another feature frequently observed: the heaviest colonization of marine algae is frequently in axillary regions, presumably where diffusion is restricted and organic matter can accumulate.

It is frequently of interest to know whether a micro-organism is actively multiplying (as opposed to merely assimilating substrate) in a particular environment at a given time. Indeed, it can be argued that it is those environments where an organism can multiply which are of most interest, since in many other environments the organism may be found in viable form, but may not be able to reproduce. We have approached this question with the use of tritiated thymidine. It is well known that cells undergoing division duplicate their DNA, whereas non-growing cells do not. Therefore, cells which are multiplying will incorporate the DNA precursor tritiated thymidine, and will become radioactive, whereas non-dividing cells will not become radioactive. We have used this technique to study the growth of filamentous bacteria of the species *Leucothrix mucor* growing epiphytically under natural conditions on marine seaweeds. We find that in a given area of an algal frond, certain *L. mucor* filaments incorporate tritiated thymidine very rapidly, but other filaments in the same region are completely non-radioactive, even though both radioactive and non-radioactive filaments appear morphologically similar. In many cases, we find that even within a single *L. mucor*

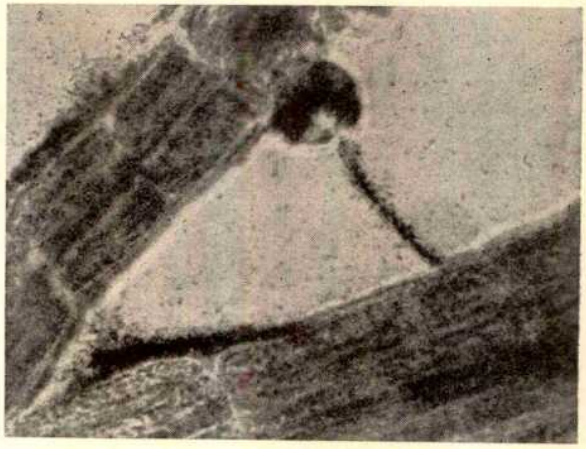

Fig. 1. Autoradiograph of red alga incubated with ^{14}C-glutamate. Incubation, May 1, 1965, 6.00–7.00 p.m., Long Island Sound, Woodmont, Connecticut. Red alga fronds taken directly from Nature, placed in a vial with 1 ml. sea water containing 1 μc./ml. ^{14}C-glutamate (27 mc./mmole), incubated *in situ* (temperature 9° C). Sample fixed overnight in 4 per cent formaldehyde, then washed in water, and affixed to slides with Ulrich's adhesive. Kodak '*NTB*-2' liquid emulsion. Exposure time, 7 days

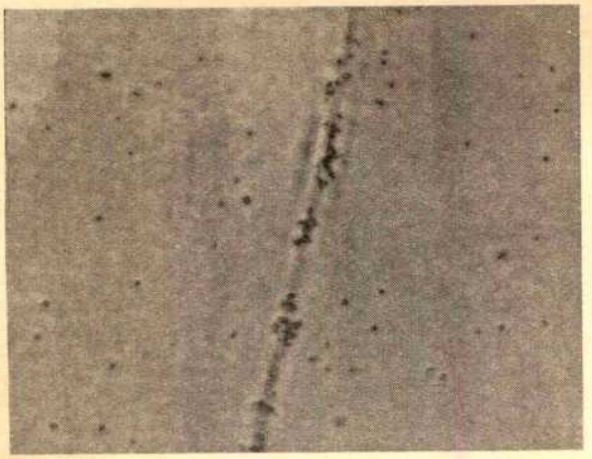

Fig. 2. Autoradiograph of *Leucothrix mucor* filament epiphytic on red alga incubated with ^{3}H-thymidine. Incubation, May 2, 1965, 3.00–4.00 p.m., Narragansett Bay, Quahaug Rock. Red alga, *Polysiphonia lanosa*, taken directly from Nature, placed in a vial with 1 ml. sea water containing 1 μc./ml. ^{3}H-thymidine (6·7 c./mmole), incubated *in situ*, temperature 12° C. Sample fixed 3 days in 4 per cent formaldehyde, then treated as in Fig. 1

filament, growth is localized, and Fig. 2 shows an example of a filament where growth is occurring in four or five localized bands. Thus we can determine by this technique the proportion of filaments, or of cells within filaments, which are growing. This same technique could be used with any other organism which is able to incorporate exogenous thymidine into its DNA.

We believe that the present technique has extremely wide application in microbial ecology, and can be adapted to a variety of problems where it is required to know something about the physiological or biochemical aspects of the organism–environment relationship. Although we have used it in the aquatic habitat, there is no reason why it could not also be applied to soil, the animal body, or the plant root. The effect of environmental changes, seasonal cycles, alterations of temperature, *p*H, and other factors on the biochemical functions of micro-organisms can now be studied for the first time directly in the natural situations which are the primary interest of the investigator. No longer need the microbial ecologist be satisfied with merely looking and counting. This technique provides a means for directly studying in Nature the behaviour of micro-organisms with only minimal disturbance to the system by the investigator.

MICROBIOLOGY

Effect of Growth Rate on the Lipase Activity of a Rumen Bacterium

In 1961 Hobson and Mann[1] reported the isolation of lipolytic bacteria from the sheep rumen. The predominant lipolytic bacteria were anaerobic, Gram-negative, vibrio-shaped organisms which were not named. Since this time other strains of these bacteria have been isolated and one (strain 5*S*) is being used in a detailed investigation of the lipolytic enzymes. Lipase activity was found to be associated with growing cells in batch culture and so the enzyme activity of the cells grown in continuous culture was tested so that the optimum activity might be obtained for further investigations. The bacterium was grown anaerobically in a medium as previously described[2] and in a chemostat essentially similar to that described by Hobson[3], but of larger vessel volume and fitted with a *p*H control system. In the results described here fructose (concentration 29 μmol/ml.) was the limiting nutrient, and the culture *p*H was controlled at 6·1–6·2, but similar results were found when glycerol was the limiting nutrient. The organism had previously been shown to hydrolyse glycerol esters of short-chain and long-chain fatty acids (tributyrin, triolein and linseed oil) but a more rapid enzyme assay was obtained using the method of Nachlas and Seligman[4] in which hydrolysis of the naphthyl esters of acetic, lauric and stearic acids is followed. The results are taken from a continuous culture run of 1,100 h, and when the culture had stabilized at each growth rate a sample (10 ml.) was taken from the culture vessel and centrifuged to compact the cells. The supernatant was pipetted off and the cells resuspended in 1·0 ml. of Veronal buffer, *p*H 6·8, containing 0·02 per cent (w/v) sodium sulphide.

A suitable volume, 0·2 ml., of the cell suspension or 0·5 ml. of the culture supernatant was then added to a test-tube containing the substrate and buffer in the proportions specified by Nachlas and Seligman[4] and the tube incubated at 38° under a stream of nitrogen which served both to keep the cells suspended and to keep the system anaerobic. The naphthol released was determined by a colorimetric method[4] after incubation for 45 min or 30 min for the laurate and acetate and 90 min for the stearate. The percentage hydrolysis of the substrate was then corrected in each case to that which would be produced by a culture of standard turbidity.

The results for stearate and acetate substrates are shown in Fig. 1. The dilution rates shown were not taken in ascending order but were taken at random to obviate any continuous change in constitution of the cells caused by growing them at a steadily increasing growth rate. The results for laurate were essentially the same as those for stearate, and a determination at a growth rate of 0·03 h^{-1} showed practically no enzyme activity. From the relative hydrolysis produced by cells and supernatant the organism would seem to produce two enzymes, an esterase associated mainly with the cells and a lipase which is mainly secreted into the culture medium.

The activities in the supernatants relative to the cells are higher than shown on the graph, as the cells equivalent to 2 ml. of culture were used in the activity digests, whereas only 0·5 ml. of culture supernatant was used. What is unusual about these results is the pronounced dependence of enzyme activity on growth rate. Superimposed on the graphs of enzyme activity is a graph of culture turbidity at the dilution rates corresponding to various steady states, from which the maximum growth rate of the bacteria in this medium can be seen. The culture turbidity has been shown to be proportional to

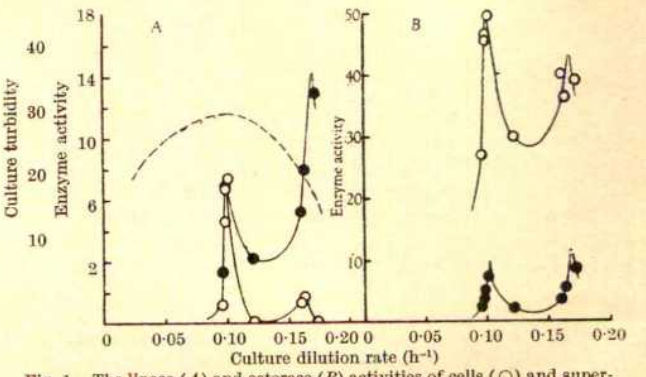

Fig. 1. The lipase (*A*) and esterase (*B*) activities of cells (○) and supernatants (●) from a continuous culture growing at different rates. Substrates, naphthyl stearate (*A*), naphthyl acetate (*B*). Superimposed on *A* is a graph of the steady-state cell concentrations at different growth rates

the concentration of cells as mg dry wt/ml. (ref. 2). There is a peak of enzyme activity at about the optimum growth rate when energy of fermentation of the substrate is being used optimally for cell formation and not for maintenance requirements, and this might be expected, but there seems to be no explanation of the second peak of enzyme activity, unless two separate enzyme systems are being formed. This will be further investigated.

The optimum growth rates for lipase and esterase activities correspond, although that the lipase and esterase activities are due to two different enzymes is suggested by the different distribution of activities shown here: the apparently different *p*H optima for activity, and the fact that when the cells are grown at a constant dilution rate of 0·1 h^{-1} the specific activity of the lipase seems to be much more dependent on the *p*H at which the culture is growing than does the esterase activity.

VIROLOGY

Early Diffuse Chromosome Alterations in Monkey Kidney Cells infected *in vitro* with Herpes Simplex Virus

Herpes simplex virus induces chromosomal alterations in cultures of Chinese hamster cells[1–4] and human cells[4]. We have observed numerous mitoses, with chromatid and chromosome gaps as well as breaks, in primary cultures of monkey cells inoculated with herpes simplex virus; with a virus–cell ratio of about 1 : 8, 25 per cent of mitoses showed such lesions 19 h after the viral inoculation; this percentage rose to 60 per cent at 27 h. Besides mitoses with one or few gaps and breaks, diffuse metaphase chromosomal alterations were observed, but only after 26 h, and then in only a very small number of cells[5].

In order to investigate more accurately the time of appearance of the chromosomal lesions, cells were infected with a high multiplicity of virus. Primary cell cultures of *Papio papio* kidney cells were made on 6 × 32 mm coverslips in Leighton tubes in a medium consisting of 47·5 parts Hanks's solution, 47·5 parts Parker's medium, and 5 parts heat inactivated calf serum. After 5 days, the average number of cells was $2{\cdot}5 \times 10^5$ per tube.

Herpes simplex virus (*HFYS*$_{21}$ strain, American Type Culture Collection) propagated in our laboratory in *KB* cells was then added; each tube received 0·3 ml. of virus suspension containing $10^{6{\cdot}5}$ *T.C.I.D.* 50, giving a virus–cell ratio of about 10 : 1.

Control tubes received the same dose of virus previously inactivated with ultra-violet irradiation. Other controls received 0·3 ml. of supernatant from uninfected *KB* cell cultures.

Microscopic observations were made at hourly intervals to estimate the gross cytopathic effect. Two replicate tubes from each of the three groups were sampled at intervals from 30 min to 4 h after inoculation, in order to examine the mitoses.

Colchicine was added to most tubes (see Tables 1 and 2), and the cultures were incubated for an additional period of 2 h. The coverslips were then removed, immersed in a hypotonic solution, fixed in Carnoy's solution, air dried, and stained with Unna-blue. Mitoses were observed using oil immersion and photographed. In order to detect early alterations and to recognize any artefact due to colchicine itself, a few tubes were incubated with colchicine for 30 min, 1 h or 1·5 h or received no colchicine at all.

The infected tubes showed no cytopathic effect until the tenth hour. At that time, the cytopathic effect appeared and increased rapidly, and the whole cell layer was destroyed by the twenty-fourth hour. In contrast, controls appeared intact at 24 h.

Tables 1 and 2 show the number and percentage of abnormal mitoses observed at early times of inoculation. In the infected tubes, the lesions were of two types: (*a*) distinct gaps and breaks, usually in one chromatid more often than in both; (*b*) diffuse lesions of many or most chromosomes. These diffuse lesions are similar to those reported by several authors[4,6,7], some of which appeared to be due to a partial despiralization of the chromosome.

The distribution of the cells in cultures was not uniform along the length of the coverslips, as the Leighton tubes were incubated in a tilted position, and it was observed that the percentage of damaged metaphases of both types was much higher where the cells were more sparse. The results given in Tables 1 and 2 are those relating to regions with a low density of cells. Gaps and breaks slowly became more numerous in the infected tubes whereas the number of diffuse lesions appeared to be very high as early as the second hour, since only one such figure was seen in the controls. Comparison of the results with those from coverslips not treated with colchicine showed that no artefact is due to the alkaloid.

In tubes not exposed to colchicine, a possible colchicine-like action of the infectious virus was noted. The chromosomes of 50 per cent of metaphases appeared well spread and condensed, whereas the figure for cells exposed to virus previously inactivated by ultra-violet light was 30 per cent and for those receiving *KB* cell culture supernatant only 25 per cent. Anaphase abnormalities and formation of micronuclei were also observed with infectious virus.

The chromosomal lesions described here are due to herpes simplex virus infection: they were not observed in controls when herpes simplex virus was previously irradiated with ultra-violet light, or when supernatant from *KB* cells was added alone. It has already been shown[5] that few or no lesions are seen if the virus is inactivated by heat or neutralized by a specific antiserum. If these results are compared with those previously reported[5] it appears that the chromosomal injuries occur much sooner with a higher virus dose and the figures for diffuse damage are surprisingly higher.

Table 1. Abnormal Mitoses after Inoculation with Infectious Virus

Time of incubation with infectious virus (h)			No. of mitoses examined	Abnormal mitoses			
Total time	Before addition of colchicine	After addition of colchicine		Few gaps and/or breaks	%	Diffuse alterations	%
1	0·5	0·5	186	8	4·3	0	0
1·5	0·5	1	112	3	2·7	0	0
2	0·5	1·5	147	8	5·5	28	18·3
2	1	1	164	12	7·3	34	20·8
3	1	2	140	6	4·3	41	29·3
3	2	1	183	20	10·9	46	24·3
4	2	2	112	9	8	35	31·2
4	3	1	147	25	16·9	45	24·5
0·5	0·5		100	1	1	0	0
1	1	No	109	4	3·6	0	0
1·5	1·5	colchicine	104	3	2·9	0	0
2	2	added	160	16	10	21	13·1
3	3		132	19	14·4	26	19·7
4	4		117	9	7·7	41	28·3

Table 2. Abnormal Mitoses in Control Tubes

Control series	Time of incubation (h)			No. of mitoses examined	Abnormal mitosis		
	Total time	Before addition of colchicine	After addition of colchicine		Few gaps and/or breaks	%	Diffuse alterations
Ultra-violet-inactivated virus	1	0·5	0·5	112	5	4·4	0
	2	1	1	90	2	2·2	0
	3	1	2	126	7	5·2	0
	4	2	2	166	3	1·8	1
Ultra-violet-inactivated virus	1	1	No	73	4	5·4	0
	3	3	colchicine	110	2	1·8	0
	4	4	added	128	6	4·7	0
Uninfected *KB* culture supernatant	1	0·5	0·5	114	7	6·1	0
	2	1	1	108	3	2·9	0
	4	2	2	105	4	3·9	0

The early appearance of such gross lesions is noteworthy; they were obvious at 2 h, that is, when about 80 per cent of the virus had been absorbed to the cells[11]. According to Roizman, these first 2 h correspond to the stage at which herpes simplex virus induces the preliminary synthesis necessary for the initiation of viral DNA duplication[8].

These diffuse chromosomal lesions could be noted 1·5 h before formation of the earliest type-*A* intra-nuclear inclusion bodies in interphase cells[9], 2 h before the onset of virus DNA synthesis[8], and 4 h before new particles could be detected inside the nucleus by electron microscopy[10].

The occurrence of early diffuse chromosome fragmentation may help to explain the apparent inhibitory effect of herpes simplex virus on mitoses[11]. Experiments are now in progress to determine whether other strains of herpes simplex virus induce the same chromosomal lesions.

Inhibition of Adenovirus 12 Oncogenicity in Hamsters by Simultaneous Inoculation with Adenovirus 5

Trentin *et al.*[1] demonstrated that hamsters inoculated at birth with adenovirus 12 develop a high incidence of malignant tumours, and that viral multiplication does not seem to occur under these conditions. On the other hand, adenovirus 5 is apparently not oncogenic for hamsters[2], but it has been reported to induce a lethal infection in new-born animals including lesions of liver cells similar to those observed in cultured human epithelial cells in which the virus is multiplying[3]. Further investigations[4] have recently shown that the pathogenicity of adenovirus 5 for new-born hamsters depends on the virus doses inoculated, no pathological symptoms being observed below 10^8 *T.C.I.D.* 50.

This communication presents results indicating that the oncogenicity of adenovirus 12 for hamsters can be reduced by simultaneous administration to new-born animals of both adenovirus 5 and 12.

Adenovirus 12 (strain Huie) and adenovirus 5 (strain Adenoid 75), supplied by the American Type Culture Collection, were inoculated on *KB* cells grown as monolayers in Roux bottles in a casein hydrolysate medium supplemented with 5 per cent calf serum and antibiotics (penicillin, streptomycin, kanamycin).

When all the cells exhibited typical cytopathic effects, they were freeze-thawed three times in dry ice–alcohol, and the cell-supernatant mixtures were centrifuged at 2,000 r.p.m. for 5 min to remove cellular debris. Supernatants, considered as virus stocks, were placed in 2-ml. vials stored at −20° C, and used for all the experiments described here.

Virus assays were carried out in *KB*-cell tubes. The final reading was made on the tenth day following virus inoculation, and *T.C.I.D.* 50 was calculated by the method of Kärber.

The titres of the virus stocks were, respectively, $10^{2.5}$ *T.C.I.D.* 50 per 0·1 ml. for adenovirus 12 and $10^{6.5}$ *T.C.I.D.* 50 per 0·1 ml. for adenovirus 5.

Litters of 1–3-day-old, male and female, non-inbred golden hamsters (*Cricetus auratus*) from a closed colony established in our Institute were randomly distributed prior to inoculation.

All animals were inoculated by the subcutaneous route in the dorsal region with an unvarying volume of 0·3 ml. The following series were established: (*a*) animals inoculated with adenovirus 12 (0·2 ml.) adjusted to a volume of 0·3 ml. with Hanks' solution; (*b*) animals inoculated with adenovirus 12 (0·2 ml.) mixed immediately before inoculation with adenovirus 5 (0·1 ml.), mixing of both viruses being carried out at room temperature in a vial by means of pipetting; (*c*) animals inoculated with adenovirus 12 (0·2 ml.) mixed under the same conditions as above, with 0·1 ml. of uninoculated *KB* cell extract.

The effects of diluting or inactivating adenovirus 5 prior to mixing with adenovirus 12 were investigated in a complementary experiment. Adenovirus 5 was diluted 10^{-3} and 10^{-6} in Hanks' solution, or inactivated by heating to 100° C for 15 min.

The hamsters were examined twice a week. Tumours were detected through palpation and confirmed at autopsy and by histological investigations. A preliminary experiment was undertaken with the view of detecting an eventual pathogenicity for new-born hamsters of adenovirus 5 *T.C.I.D.* 50 used in our experiments. No clinical manifestations of disease were found in fifteen hamsters observed for over 1 year.

Table 1 shows a summary of the results of three independent experiments which were performed under identical conditions, in which adenovirus 5 was mixed undiluted with adenovirus 12. These results indicate that significant decrease of the percentage of adenovirus-12 induced tumours in hamsters can be achieved by simultaneous injection of adenovirus 5 into new-born animals.

Table 2 shows the results of experiments in which adenovirus 5 was diluted or inactivated prior to mixing with adenovirus 12.

Table 1. Inhibition of Adenovirus 12 Oncogenicity in Hamsters by Simultaneous Inoculation with Adenovirus 5

Experiment	Composition of inoculum	No. of viral infective doses inoculated (*T.C.I.D.* 50)	Observation period (days)	Tumorous hamsters / Injected hamsters *	Tumorous hamsters (%)	Statistical evaluation †
1	Adeno 12 (0·2 ml.) + Hanks' (0·1 ml.)	632		19/23	82·6	
	Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632 $3·16 \times 10^6$	360	4/12	33·3	$P = 0·01$
2	Adeno 12 (0·2 ml.) + Hanks' (0·1 ml.)	632		7/8	87·5	
	Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632 $3·16 \times 10^6$	240	1/6	16·6	$P = 0·03$
3	Adeno 12 (0·2 ml.) + Hanks' (0·1 ml.)	632		9/16	56·2	
	Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632 $3·16 \times 10^6$	210	0/13	0	$P = 0·005$
4 (controls)	Adeno 12 (0·2 ml.) + Hanks' (0·1 ml.)	632		7/8	87·5	
	Adeno 12 (0·2 ml.) + Uninoculated *KB* cell extract (0·1 ml.)	632	240	7/8	87·5	

* Numerator indicates No. of hamsters which developed tumours and denominator No. of hamsters surviving at weaning (3 weeks).
† Corrected χ^2 tests.

Table 2. Effect of Inactivating or Diluting Adenovirus 5 on the Inhibition of Adenovirus 12 Oncogenicity

Composition of inoculum	No. of viral infective doses inoculated (*T.C.I.D.* 50)	Observation period (days)	Tumorous hamsters / Injected hamsters *	Tumorous hamsters (%)	Statistical evaluation †
Adeno 12 (0·2 ml.) + Hanks' (0·1 ml.)	632	210	7/8	87·5	—
Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632	210	7/8	87·5	$P > 0·05$
	0 (virus inactivated)				
Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632	210	8/11	72·7	$P > 0·05$
	3·1				
Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632	210	4/10	40	$P > 0·05$
	3,160				
Adeno 12 (0·2 ml.) + Adeno 5 (0·1 ml.)	632	210	1/6	16·6	$P = 0·03$
	3,160,000				

* Numerator indicates No. of hamsters which developed tumours and denominator No. of hamsters surviving at weaning (3 weeks).
† Each series of animals inoculated with adenovirus 12 and various adenovirus 5 doses was compared with the series of animals inoculated with adenovirus 12 and Hanks' fluid by means of corrected χ^2 tests.

It can be seen that: (*a*) High doses of adenovirus 5 (3×10^6 *T.C.I.D.* 50) are apparently required to afford protection from tumour development. (*b*) Lower doses of adenovirus 5 are not effective in preventing the induction of tumours. (*c*) Protection from tumour growth cannot be obtained by inoculation of heat-inactivated adenovirus 5.

Experiments are now being carried out in our laboratory to determine whether the protection afforded to hamsters is linked with adenovirus 5 virions or with a soluble factor present in adenovirus 5 cultures. If the former hypothesis is correct, several explanations can be invoked, such as a direct interference phenomenon or an immunological mechanism.

VETERINARY SCIENCE

A New Sterilizing and Hereditary Defect (the 'Dag Defect') located in the Bull Sperm Tail

Hitherto, cases of sterility in the bull, where the abnormal sperm population shows a dominant sperm defect mainly or exclusively located in the spermatozoan tail, have only rarely been reported.

Hancock and Rollinson[1] found in the Guernsey breed the so-called 'decapitated sperm defect', a congenital defect showing 95–100 per cent of the spermatozoan heads detached from the still motile spermatozoan tails. According to Jones[2], this defect is hereditary within the Guernsey breed.

Williams[3] found in man what he called a 'centriolar-mitochondrial defect' in less than 0·5 per cent of his cases of sterility, often involving the entire sperm population. The defect is characterized by a prolongation or thickening of the mitochondrial sheath and is often combined with a lack of the main piece of the tail. Savage and Isa[4] and Coubrough and Barker[5] have found similar cases of spermatozoan tail defects in bulls of different breeds, but so far there is no report of any of these cases being of congenital nature.

A characteristic sterilizing abnormality, the 'corkscrew sperm defect' located in the middle piece, was demonstrated in bulls of the RDM breed[6]. A more detailed investigation of this defect showed an irregular distribution of the mitochondrial sheath in smaller or bigger lumps along the middle piece[7]. This also provides an explanation for the high incidence of persistent proximal droplets in many of the affected sperms. The defect has since been demonstrated also in the Jersey, Frisian and Aberdeen Angus breeds, and usually the bulls in question have shown a normal spermiogram and normal fertility up to the age of 5–10 years (unpublished observations).

Swanson and Boyd[8] have reported in detail their investigations of three bulls of the Jersey breed which showed a high percentage (50 per cent or more) of coiled, looped or bent spermatozoan tails. Their illustrations, and moreover the fact that spermatozoan material taken from cauda epididymidis *post mortem* showed practically normal tails, seem to indicate that in these cases the prevailing tail defect was the well-known secondary sperm defect: *bent tail*[9]. Usually the bent tail defect takes the form of a single bending of the tail at the distal end of the middle piece, with or without the presence of the distal cytoplasmic droplet within the loop.

Also in a recent case of akinesia of bull sperm reported by Gustafsson[10] the dominating type of sperm abnormality seems to have been the simple bent tail, and electron-microscopical investigations did not show any pathological changes in the ultrastructure of the sperm.

The case histories reported here refer to two 'full-brother' bulls of the Jersey breed, both sub-fertile and both showing the same abnormal spermiogram characterized by a high percentage of defective spermatozoan tails.

A semen sample from bull *A* ('Dag', 11 months old) was received from an artificial insemination (A.I) centre for routine brucellosis control in October 1963. It was the first time that the bull had been used, and the sample (3 ml.) was normal in most respects (concentration about 1 million spermatozoa/mm^3) except that motility was very low and the spermiogram showed a very peculiar picture. There were very few defects among the spermatozoan heads, but about 40 per cent of the spermatozoan tails were strongly coiled, folded together or split up into fibres. Such a high rate has not been seen before (Fig. 1). After retesting several times during the next two months, when similar results were obtained, the A.I. centre was informed that the bull would probably show a lowered fertility and therefore could not be recommended for A.I. Consequently the bull was sold to a private breeder for natural service within his own herd. During the spring of 1964 it was used for 30 cows and heifers (2–3 matings each) with very little success (only one cow conceived). Finally, the bull was taken over by the laboratory for final investigation.

As members of the Jersey Committee of the A.I. centre were still very interested in the sire–dam combination of the bull 'Dag', his full-brother (case *B*), who was born during November 1963, was purchased for the centre. When this younger brother was about 11 months old, the first semen samples were collected and examined, with the astonishing result that they showed almost the same quality semen as that of bull *A*: *Sperm concentration*, about 0·7 million spermatozoa/mm^3 or slightly lower; *motility*, low (10–15 per cent) with weak sperm movements; *morphology*, 40–50 per cent strongly coiled, folded or broken sperm tails (Fig. 3). A total of eight ejaculates (including II and III ejaculates) from bull *B* were examined, all with the same result. The semen was used for insemination (dilution 1 : 10) of sixteen cows and heifers, with rather limited success (only three conceptions were recorded). The bull was slaughtered when 13 months old.

Bull *A* was kept at the experimental farm of the laboratory until it was 2¼ years old. A total of eleven ejaculates were examined from this bull during the observation period, and no improvements in the semen quality were observed.

Post-mortem examination of the genital organs of the two bulls gave the following results: testis + epididymis normal in shape and size; weight: bull *A*, 370 + 380 g, and bull *B*, 340 + 330 g. Histology of testis was normal; no signs of degeneration or inflammation could be demonstrated in the spermiogenic epithelium.

Sperm concentrates from ampulla ductus deferentis and cauda epididymidis were collected. In bull *A*, a haemocytometer count of the cream-like fluid from ampulla ductus deferentis showed a concentration of 9–10 million spermatozoa/mm³. Slides were prepared from these concentrates and stained in the same way as the ejaculates by the eosin–nigrosin and indian ink methods. In both bulls the differential counts of the ampulla ductus deferentis and the cauda epididymidis material gave similar results to those already recorded for the ejaculates, namely, 40–50 per cent of all the sperm tails were strongly coiled, folded or broken (Figs. 2 and 4). In some not too crowded areas of 5μ sections from the cauda epididymidis, it was also possible to demonstrate the typical coiled or folded sperm tails.

It would be of the greatest interest to trace a number of bulls closely related to bulls *A* and *B*, and to investigate their spermiograms. The sire of the two bulls is still in use at a Danish A.I. centre. That animal has been examined once a year during the period 1959–64, and has always showed a normal semen picture. No period of infertility has been observed. Half-brothers to bull *A* and *B* are also in use at different A.I. centres (two on the sire-side and two on the dam-side) and all four are normal so far as semen and fertility are concerned.

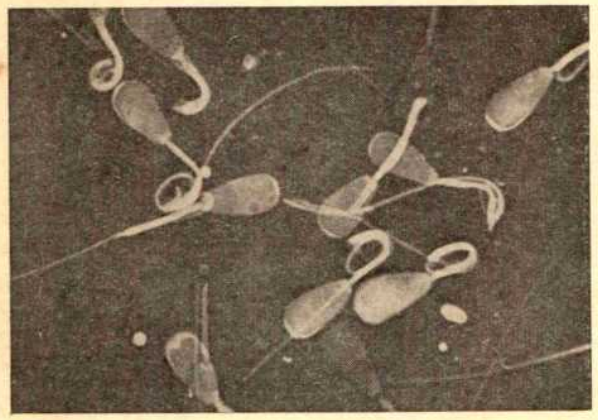

Fig. 1

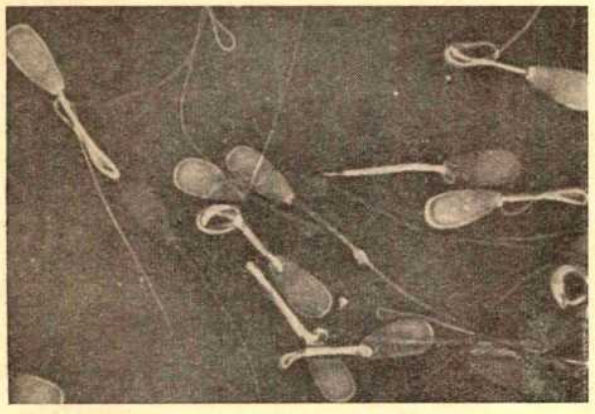

Fig. 2

Figs. 1 and 2. Photographs showing the typical spermatozoan tail defect in smears from bull *A*. Fig. 1 has been prepared from the first ejaculate examined of the bull. Fig. 2 shows the morphology of the sperm-concentrate from ampulla ductus deferentis at slaughter 16 months later. (Eosin-nigrosin stain, × 1,000)

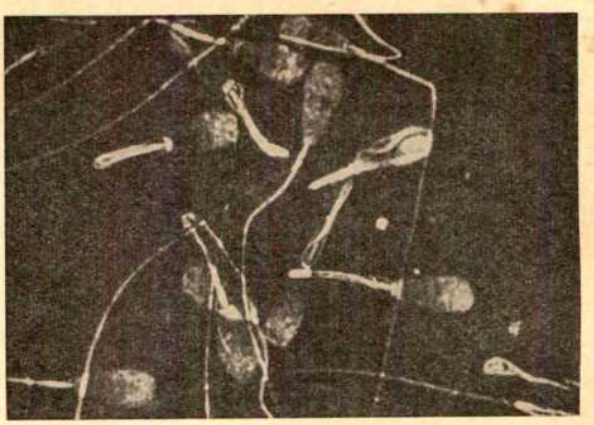

Fig. 3

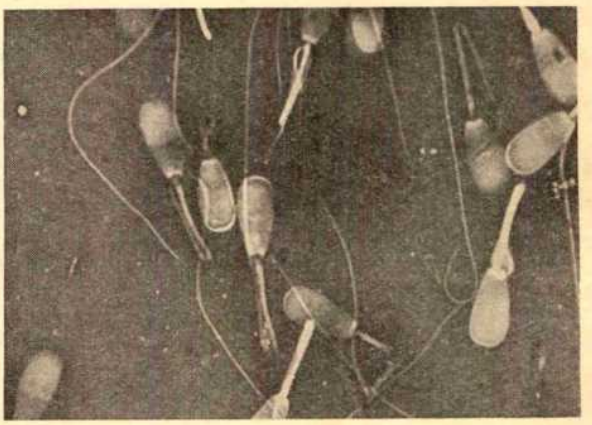

Fig. 4

Figs. 3 and 4. Photographs showing the typical spermatozoan tail defect in smears from bull *B*. Fig. 3 shows the defects in an indian ink preparation from ejaculated semen. Fig. 4 demonstrates an eosin-nigrosin smear from the contents of cauda epididymidis at slaughter, 2 months later (×, 1,000)

The two cases reported are especially remarkable because they are found within the Jersey breed where so far congenital and hereditary defects have only rarely been found. It would appear that a fundamental defect in the sperm tail structure has occurred as the result of the specific sire–dam combination used, and a closer investigation by means of the electron microscope would probably provide a more detailed explanation.

These findings seem to indicate that 'strongly coiled and folded tails' should always be included in the group of 'primary sperm abnormalities'[9] in the morphological sperm examination for fertility in the bull.

Thanks are due to Dr. J. Müller, head of department, for his assistance in preparing the photo-micrographs.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, February 14

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 5.15 p.m.—Prof. Theodor Bücher (University of Munich): "Dynamics of Liver Metabolism". (Further lecture on February 17.)*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. James D. Ebert (Carnegie Institution of Washington). "Interacting Systems in Development: I. Beyond the Ribosome".*

Tuesday, February 15

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Meeting on "Barley".

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m.—Dr. Elliott Jaques: "The Nature of Decision-Making".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. R. May: "Colonial Morphology, Antigens and Pathogenicity of Haemophilus Influenzae". (Tenth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. James D. Ebert (Carnegie Institution of Washington): "Interacting Systems in Development: II. Biochemistry and Physiology of the Developing Heart". (Further lecture on February 17.)*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Dr. Vassos Karageorghis: "Recent Excavations in the Archaic Necropolis of Salamis".*

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Chemistry Lecture Theatre, Queen Elizabeth College, Campden Hill Road, London, W.8), at 6.30 p.m.—Scientific Films.

Wednesday, February 16

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the Fine Chemicals Group and the Microbiological Group, at Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), from 3 p.m. to 6.45 p.m.—Meeting on "The Cephalosporin Story: Biosynthesis—Chemistry—Pharmaceutical Aspects". Lecturers: Dr. G. G. F. Newton, Dr. A. G. Long and Dr. P. W. Muggleton.

UNIVERSITY OF LONDON (at the Institute of Dental Surgery, Eastman Dental Hospital, Gray's Inn Road, London, W.C.1), at 5.30 p.m.—Dr. J. A. Fraser Roberts. "The Genetic Element in the Causation of Disease". (First of three lectures on "The Scientific Basis of Dentistry" organized by the British Postgraduate Medical Federation.)*

INSTITUTE OF INFORMATION SCIENTISTS (at the Whitehall Hotel, Bloomsbury Square, London, W.C.1), at 6.15 p.m.—Mr. J. McDaniel: "Recent Developments in Mechanical Translation".

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (in the Physics Block, Imperial College of Science and Technology, London, S.W.7), at 6.30 p.m.—Dr. M. F. Ansell: "Recent Advances in the Chemistry of Unsaturated Acids".

Thursday, February 17

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (joint meeting with the Road and Building Materials Group, at 14 Belgrave Square, London, S.W.1), at 2.30 p.m.—Meeting on "Aspects of the Surface Chemistry and Practical Application of Bitumen Emulsions".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. A. G. Atkins and Dr. D. Tabor, F.R.S.: "Strength Properties of Solids at Very High Temperatures"; Mr. J. W. Steeds: "Dislocation Arrangements in Copper Single Crystals as a Function of Strain".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Symposium on "Intertidal Studies at Scolt Head, Norfolk".

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. J. Dieudonné: "The New Algebraic Geometry".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Mechanized Permanent Way Maintenance", introduced by Mr. F. Fawcett and Mr. A. C. Edrich.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. F. Soothill: "Quantitative Disturbances of Plasma Proteins in Disease". (Eleventh of fifteen lectures on "The Scientific Basis of Medicine", organized by the British Postgraduate Medical Federation.)*

SOCIETY FOR ANALYTICAL CHEMISTRY, PARTICLE SIZE ANALYSIS GROUP (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Inaugural Meeting, followed by Scientific Papers.

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with West Ham College of Technology Chemical Society, at the West Ham College of Technology, Romford Road, London, E.15), at 7.30 p.m.—Mr. W. G. Busbridge. "The Use of Radioisotopes".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. G. Webbe and Dr. P. Jordan: "Recent Advances in the Knowledge of Schistosomiasis in East Africa".

UNIVERSITY OF LONDON (at Wye College, near Ashford, Kent), at 8.15 p.m.—Prof. E. W. Russell: "The Application of Agricultural Science to Tropical Agriculture".*

Thursday, February 17—Friday, February 18

ASSOCIATION OF APPLIED BIOLOGISTS, AND THE BRITISH MYCOLOGICAL SOCIETY (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 11 a.m. daily—Symposium on "Physiology of Parasitism".

Friday, February 18

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, Institute House, 32 Welbeck Street, London, W.1), at 2 p.m.—Radiobiology Meeting.

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Captain A. Wepster: "Navigation in Main Western European Rivers".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. E. J. Denton, F.R.S.: "The 'Mirrors' of Fishes".

Saturday, February 19

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Frank W. Lane: "The Elements Rage—Storm, Flood and other Forms of Violence in Nature".*

Monday, February 21

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Lt. Col. J. A. Simson, M.C., and Mr. C. J. Sweeney, O.B.E.: "The Ordnance Survey and Land Registration".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. J. C. Wood: "Developments in the Control of Ectoparasites of Livestock".

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. F. Bourlière (University of Paris): "The Ecology of Herbivores in the African Savanna and Forest". (Further lecture on February 23.)*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GEOLOGISTS (4) (40 or under, with a degree, or equivalent with a pass in geology at final examination) IN THE GEOLOGICAL SURVEY OF THE DEPARTMENT OF INDUSTRY AND COMMERCE—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin, 1, Republic of Ireland (February 17).

ASSISTANT LECTURER OR LECTURER IN THE FIELD OF STATISTICS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (February 19).

CHEMIST (with a degree or equivalent qualification in chemistry and preferably a knowledge of chromatographic techniques) to assist in developing and applying analytical techniques for insecticide residues associated with studies on the behaviour of insecticides in soils and plants—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (February 19).

EXPERIMENTAL OFFICER or SENIOR EXPERIMENTAL OFFICER (with a university degree or H.N.C. and preferably a special knowledge of digital electronics and data handling systems) IN THE DEPARTMENT OF PHYSICS OF THE FACULTY OF SCIENCE, to take part in the experimental programme in nuclear physics associated with the Heavy Ion Linear Accelerator and other accelerators—The Registrar, The University, Manchester, 13, quoting Ref. 17/66 (February 23).

LECTURER (preferably with a veterinary qualification and interested in chemical pathology) IN THE DEPARTMENT OF PATHOLOGY—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (February 25).

ELECTRON MICROSCOPIST (with experience in the use of the electron microscope in biological research, and preferably with a degree or equivalent qualification) IN THE DEPARTMENTS OF BIOLOGICAL CHEMISTRY AND PHYSIOLOGY, to take charge of the electron microscope serving these two departments and, for the present, certain others—The Secretary, The University, Aberdeen (February 26).

LECTURER or ASSISTANT LECTURER IN STRUCTURES IN THE DEPARTMENT OF ENGINEERING IN THE FACULTY OF SCIENCE—The Registrar, The University, Manchester 13, quoting Ref. 19/66/Na (February 26).

READER IN MICROBIOLOGY IN THE DEPARTMENT OF BOTANY; and a LECTURER (preferably with a special interest in enzymology) IN BIOCHEMISTRY—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (February 26).

UNIVERSITY LECTURERS (2) IN THE DEPARTMENT OF METALLURGY—The Secretary of Faculties, University Registry, Oxford (February 26).

CHAIR OF ARCHAEOLOGY—The Secretary, The University, Southampton (February 28).

ENTOMOLOGIST (under 40) on the scientific staff of the Royal Horticultural Society at Wisley, for duties which are principally advisory and instructional, but may include investigations on insect pests affecting horticultural plants—The Secretary, Royal Horticultural Society, Vincent Square, London, S.W.1, marking envelope "Confidential" (February 28).

JUNIOR LECTURER/LECTURER IN CHEMISTRY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, February 28).

LECTURER or ASSISTANT LECTURER (preferably with a special interest in operational research and/or statistics) IN THE ELECTRONIC COMPUTING LABORATORY—The Registrar, The University, Leeds, 2 (February 28).

LECTURER TO SPECIALIZE IN ANIMAL NUTRITION IN THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY—The Registrar (Room 39, O.R.B.), The University, Reading (February 28).

LECTURER (with special qualifications in the teaching of biology, and if possible teaching experience in other subjects) IN EDUCATION—The Registrar, King's College (University of London), Strand, London, W.C.2 (February 28).

READER IN INORGANIC CHEMISTRY; and a SENIOR LECTURER/LECTURER IN ANALYTICAL CHEMISTRY—The Staff Officer, The College of Advanced Technology, Gosta Green, Birmingham, 4, quoting Ref 451/2 (February 28).

SENIOR RESEARCH OFFICER (with a higher degree in biochemistry or chemistry and several years' experience in research) IN MOLECULAR BIOLOGY to be engaged full-time in research in the field of protein chemistry—The

Director of Research, Dr. P. Edman, St. Vincent's School of Medical Research, Victoria Parade, Fitzroy, N.6, Victoria, Australia (February 28).

Temporary Lecturer or Temporary Assistant Lecturer in Mathematics—The Registrar, The University, Keele, Staffs (February 28).

Veterinary Officer (member of the Royal College of Veterinary Surgeons and preferably with experience of exotic as well as domestic animals), to be in charge of a well-equipped animal hospital, and to collaborate with Curators over all matters of animal welfare and husbandry—The Secretary, The Zoological Society of London, Regent's Park, London, N.W.1 (February 28).

Assistant Lecturer in the Department of Medical Physics—The Secretary, Royal Free Hospital School of Medicine (University of London), 8 Hunter Street, London, W.C.1 (March 1).

Imperial Chemical Industries Research Fellows (normally below the age of 30 with the degree of Ph.D. or with equivalent research experience) in Chemistry, Physics, Metallurgy, Engineering, Geology, Agricultural Science or related subjects—The Registrar of the University of Wales, University Registry, Cathays Park, Cardiff (March 1).

Lecturer or Assistant (Assistant Lecturer) in Electron Microscopy in the Department of Genetics—Secretary of the University Court, The University, Glasgow (March 1).

Secretary (with a good professional qualification in physics and experience in administration) of The Institute of Physics and The Physical Society—Sir James Taylor, M.B.E., F.Inst.P., Honorary Treasurer of The Institute of Physics and The Physical Society, 47 Belgrave Square, London, S.W.1, marking envelope "Personal" (March 1).

Whitley Professor of Biochemistry—The Registrar, University Registry, Oxford (March 3).

Senior Lecturer or Lecturer in Mathematics at the University of the West Indies, St. Augustine, Trinidad—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (March 4).

Assistant Lecturer or Lecturer in the Department of Zoology—The Registrar, The University, Leeds, 2 (March 5).

Post-Doctoral Research Fellow in the Department of Chemistry, University of Ibadan, Nigeria, to carry out studies on the comparative physical chemistry of haemoglobins—The Inter-University Council, 33 Bedford Place, London, W.C.1 (March 7).

Research Fellow in the Department of Statistics of the Research School of Social Sciences, Institute of Advanced Studies, Australian National University, to work in the field of mathematical statistics and its applications to other sciences—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 11).

Research Assistant (graduate, or equivalent, in physics, engineering or textile technology) to work on the development of woven, knitted and other fabrics in the Department of Textile Technology—The Registrar, Manchester College of Science and Technology, Sackville Street, Manchester, 1 (March 15).

Research Assistant (graduate or person of equivalent status) in the School of Chemistry to be responsible for the maintenance of a mass spectrometer, type MS9, and for recording and interpreting spectra—The Registrar, University of Bristol, Senate House, Bristol 2 (March 15).

Senior Lecturer (with a higher degree in pharmacology, physiology, medicine or pharmacy) in the Department of Pharmacology—The Clerk to the Council, School of Pharmacy (University of London), 29/39 Brunswick Square, London, W.C.1 (March 25).

Assistant or Associate Professor in the Department of Physics—J. M. Robson, Chairman, Physics Department, University of Ottawa, Ottawa 2, Canada.

Biologist (with a good honours degree and preferably some research experience) to join a small team carrying out research in the fields of protein chemistry; and a Physical Chemist or a Physicist (graduate) to take part in research and development work connected with the production and properties of powders—The Director of Research, The Research Association of British Flour-Millers, Cereals Research Station, Old London Road, St. Albans, Herts.

Chair of Geography—The Registrar, University Senate House, Bristol, 2.

Head (suitably qualified and experienced to supervise teaching and ancillary staff and 150 students following a full-time pharmacy course) of the New Zealand School of Pharmacy—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1; or The Director of Education, Private Bag, Wellington, New Zealand.

Master to teach Mathematics up to advanced and scholarship levels—The Rector, The Edinburgh Academy, Henderson Row, Edinburgh, 3.

Master to teach Physics at all levels up to University Scholarship—The Headmaster, Mill Hill School, London, N.W.7.

Research Assistant for a research programme entitled "An Investigation of Plant Indicators of Mineralization" being conducted by Prof. Monica M. Cole, Head of the Department of Geography at Bedford College—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1.

Senior Research Officer with primary duties in field research, but also some lecturing, etc.—The Director, Edward Grey Institute of Field Ornithology, University of Oxford, Oxford.

Visiting Professor (with a degree from a university in Great Britain, member of a professional institution and relevant industrial experience) of Ferrous Production Metallurgy at Banaras Hindu University, Varanasi, India—The Recruitment Division, The British Council, 65 Davies Street, London, W.1, quoting Ref. D20/65/UNI/9.

PRECISION ULTRAVIOLET AND VISIBLE SPECTROSCOPY FOR £815

SP500

The Unicam SP500 Ultraviolet and Visible Spectrophotometer is available complete for mains operation for £815.*

This well tried and proven instrument is to be found in laboratories throughout the world where its accurate, reliable performance has set new standards.

With the Unicam SP500 there are no extras required for normal operation—the price includes everything necessary for precision all-mains operation, deuterium lamp supply, 115 D power supply and SP549 internal power unit—right down to four glass and two silica cells in cases and a set of dust covers. In the U.K. installation is free. All you provide is your sample.

Write for the SP500 booklet today. *U.K. Price

THE IMPACT OF SOCIETY ON SCIENCE

IN his presidential report to the Carnegie Institution of Washington for 1964–65*, Dr. Caryl P. Haskins once again sustains the sweep and balance, the insight and judgment, which have made these annual presidential surveys as welcome and as stimulating in Europe as they are in the United States.

Dr. Haskins begins by announcing his primary concern with the future of science in the United States, the nature of its growth, its place in society, the quality of its evolution and its rank among the deepest values of the American people. Any examination of such questions, with the penetration and perspective that have characterized Dr. Haskins's reports, inevitably is of considerable interest and validity far beyond the national scene with which it is primarily concerned: his address is once again of deep interest to all concerned with science, whether with the evolution of science itself over the next two decades or with the relations of science to modern society.

Dr. Haskins's report might well be described—and with some justification—as an essay on the impact of society on science. He adopts a historical approach, treating the past history of science as a prologue and using as illustrations the work of Galileo Galilei and Mendel. The great disciplines, for which the anniversaries of Galileo's birth and Mendel's paper commemorate major turning points, are once again so transforming our visions, both of our outer universe and of our inner worlds, as to constitute in our time what may be reckoned as a contemporary scientific revolution fully comparable with earlier ones that are now classic. No later scientific revolution, he observes, has stood apart from the source-stream of that dramatic Greek period when science may literally have been born. In substance as in philosophy, each later burst of scientific growth has been deeply nourished by its heritage of earlier discovery and concept, transmitted in a continuous, if often tortuous, flow.

He holds, moreover, that, however fragmented the course of science may appear when viewed in any of its detailed reaches, it has, in its deeper and more general features, preserved a striking unity over the centuries. He is not, in truth, greatly concerned with the structure of scientific revolutions, and it will be apparent that he is far asunder from Prof. R. S. Kuhn and that his treatment is simpler. He stands rather with Dr. S. Toulmin, noting that while the evolution of the substance of science is—of its very nature—free and untrammelled and not to be confined within the bounds of detailed forecast, the methods of probing Nature have varied widely among different branches of science, sometimes even being in opposition. He shows that, even within a single discipline, the philosophy of approach may change drastically as the field evolves.

Dr. Haskins notes, moreover, a further point which is of special importance at the present time, and this he develops as a main theme. Each burst of scientific growth has been closely linked with the technology of its time, sensitive to the technical needs and demands of its society, profoundly influenced by them, and profoundly affecting them in turn. It is in the context of these profound interactions that he considers the relations between science and technology and the implications and the dangers attendant on the passage of the patronage of science to Government agencies and ultimately to the general public which supports those agencies. Both the magnitude and the proportion of the support which science draws from Government sources are often almost indistinguishable from support for technology. In effect, this support is ultimately apportioned according to the public will and is likely to increase still further.

Already, however, science in the United States, as in Britain, is materially endowed at a level which is unique in the history of man, and at a level also that already seriously taxes our human resources. That is the real reason why widespread understanding of the nature of science, of its distinction from technology, and of the requirements for healthy scientific growth is of increasing and critical importance. Only to a minor extent is support for science to-day drawn from the kind of patrons to whom it had become adjusted during its long formative centuries, and who in turn had become adjusted, in a considerable degree, to its demands and needs.

Dr. Haskins points out that in the past the great successes of science have depended not only on the abilities of scientists themselves but also on the understanding, patience and perceptiveness of supporting patrons. The demand for such understanding is now made not on the few but on the many, on an infinitely greater scale and on a plane far more difficult and more powerful. Meeting this demand is ultimately a problem of education and of communication, of marshalling our developing resources in those two fields to meet our pressing obligations effectively and urgently. Dr. Haskins's two vignettes are well chosen to show just how, in this way, the future of science as a dynamic cultural force in society will be determined.

In the first place, these vignettes well illustrate the pace of change and the limits of our ability to predict the implications of scientific advance and of the impact of science on society. We are scarcely aware, for example, of the potentialities of many of the new tools developed in the past decade. By far the most easily projected visions of the future are those concerning technology and scientific application, and these, precisely because the consequences of advances in science itself, are less predictable. Danger arises in the failure to distinguish between science and technology. There are also, indeed, wide differences in the contours of advance and strategies of attack between different branches of science. Dr. Haskins observes that in many important respects the development of strategy, and indeed of detailed philosophy, has been almost opposite in the physical and in the biological sciences. Concepts and approaches that have proved unsuitable in the past in one area have on occasion been highly evocative in another.

Furthermore, strategies of investigation and foci of interest have often shifted radically during the evolution of a single science. He quotes Sir Peter Medawar's view that the sheer factual content of specific scientific fields is likely to diminish with their growth, rather than pile up over the years to yield even greater and more un-

* Carnegie Institution of Washington. *Report of the President*, 1964–1965. Pp. 73. (Washington, D.C.: Carnegie Institution of Washington, 1965.)

assimilable masses. The great frames of investigation, like astronomy and the biological sciences, however, have continued to build steadily over the centuries. To-day they are frontiers as vital as ever and it is almost inconceivable that they will not maintain that vitality into the foreseeable future.

Dr. Haskins notes one aspect of the critical periods of fundamental change wrought by science which has characterized them since that period of Greek thought in which the scientific mode originated: their remarkable brevity. He suggests that one of the more important lessons of the past is that the eras of major change characteristically ran swift and deep and were incredibly dynamic. Furthermore, periods of intense change have tended, on the whole, to alternate with quieter periods of consolidation. An important factor here is possibly the real need, following a time of violent change, to pause and consolidate, to re-weave the torn fabric of universal ideas. If this factor was and is really significant, Dr. Haskins suggests that, as the pace and variety of scientific advance increase, we may well look for important shifts of pattern. Major sweeps in our ideas about the nature of the universe may not coincide precisely with periods of major growth in our ideas about, for example, the nature of life. We may come to live almost continually, not only with technical change itself but also with a plethora of revolutionary ideas.

That might almost be our present situation and it carries psychological hazards of which we should be sensitively aware. In any event, mankind is undoubtedly in the midst of an era of change in total outlook fully comparable with that of the classic scientific revolutions. Our technological society, however, shows little awareness of the real implications in its efforts to develop institutions to meet our changing needs. The extraordinary degree to which both the substantive content and the character of development of the earlier revolutions reflected and responded to the predominant and technical environments and the social and technical demands of their times is seldom considered. Nor is it always remembered that science seems to have flourished most, and made its richest contributions, in an atmosphere that combined the elements of a maximum freedom of enquiry with those of a lively—though often incoherent—stimulus of social demand and need.

It is in this context that Dr. Haskins considers the nature of the predominant claims made on the contemporary scientific revolution and of the stimuli given to it by our own environment in the years ahead. Both for science and technology the intricate social milieu of our day is, in many respects, a world society, but Dr. Haskins suggests that it is already apparent that in the future the environment created by humanity itself, the environment of human social forms, of individual human needs, must rank high in our reckoning and may equal or surpass more traditional concerns in its relevance and import. This predominant feature of our world must clearly have a profound influence in defining new sectors to command scientific attention, and could be a dominant factor in the internal growth of science.

The development of science in its relations to the society it serves, and of which it forms an integral and decisive part, is another matter, and Dr. Haskins suggests that this influence of society on science is made trebly important by the dynamic growth of our civilization and by its changing concerns and character. He sees science, indeed, as one of the cultural elements of our age, but he also recognizes that the effects on society of, for example, automation raise large questions of social and intellectual satisfaction for individuals. Dr. Haskins sees that science will not make its full contribution to the growth and welfare of society unless the nature and purpose of science are far more widely and deeply understood. There is a genuine social peril in the popular notion of the fragmentation of science, when the distinction between method and goal is not understood and the picture of fragmentation is extended to the modes of the search for knowledge.

Dr. Haskins notes the consequences for science itself if the idea that the whole search for truth leads not to a single coherent vision but to fragmentation. He suggests that we may come to think of scientific truth as being above all else a measure of the coherence of systems of thought and of their capacity to communicate among themselves; as a property primarily of interchangeability both among observers and among scientific propositions relating to differing situations in Nature. If the primary task of science remains the search for truth in such a definition, we may well conclude that the highest aim of scientific enquiry is to make knowledge communicable in all possible situations and that the measure of the validity of such knowledge may be the degree of its coherence among such situations. In striving towards such an objective, the fear of losing overriding purpose loses its reality in a scientific content.

There remains, however, a considerable hazard for the relation of science to our changing society, to which Dr. Haskins now directs attention. If the world remains free from major military conflict, what is likely to happen to the public understanding and evaluation of the scientific outlook in a materially opulent society, which provides generously for the individual wealth and leisure of its citizens? There is a widespread disposition to equate science and its purposes primarily with the two great technical areas of military defence and protection against bodily ills. The public esteem of science is strongly coloured by these identifications, and Dr. Haskins asks whether public concern for the military aspect of technology may not wane in long years of freedom from the threat of military conflict, and wonders how this will affect popular concern with science itself. Furthermore, the tendency to confuse the objectives of technology in general with those of science, although a natural misconception, is too prevalent. In the United States, technology and science have from the beginning served in the closest partnership, the one being indispensable to the other, and throughout the modern world, wherever technology is strong and well-developed, there is also science. Where one is weak the other cannot be strong. Yet their objectives differ in some important respects and the perception of these distinctions is fundamental to a genuine understanding of science.

At this point, Dr. Haskins looks again at the past, where the primitive roots of science and technology once lay far apart. A well-developed technology could and did flourish, for example, in the India and China of Lao-tse, Confucius and their contemporaries, but a scientific evolution was not possible in that philosophical climate. This difference between science and technology remains to-day, and is epitomized by their widely divergent objectives. At one extreme of the spectrum from science through technology, the essential purpose of science is the broadening of knowledge, the deepening of understanding. At the other extreme of the spectrum, the ultimate merit of technology is the effectiveness with which it can bend the knowledge won by science to real social use.

In this comparison, the attitudes and goals of technology, its procedures and its practical scale of values, may approach the general daily working philosophy of society as a whole, rather than the philosophy of science itself. In fact, the characteristic processes and goals of technology are commonly far more visible to a society than are those of its science. This immediate visibility of the aims of technology is enhanced by the circumstance that technology, unlike science, normally produces conspicuous and useful products, which, devised as they ordinarily are with the aid of the knowledge that science provides, are liable to be popularly attributed to science itself. This gives rise to the danger with which Dr. Haskins is fundamentally concerned in his review; in a society as technologically polarized as our own, public misunderstanding of the nature of science and the requirements for healthy scientific growth could, in the long run, seriously jeopardize the quality of science itself. Under such conditions the approaches and goals of science could be subjected, however gently or subtly, to assessments and demands formulated primarily in those terms.

Dr. Haskins's plea for special vigilance on this score in the years ahead, as both the magnitude and proportion of the support of science from Government sources—often almost indistinguishably bound up with support for technology, and in effect ultimately apportioned according to the public will—increase still further, is substantiated by developments in Britain in the past 2 years. It may as yet be too soon to judge whether the Ministry of Technology is really closer to industry than the Department of Scientific and Industrial Research, but there is little evidence that the creation of a Ministry of Education and Science in place of a Ministry for Science offers any advantage. On the contrary, there is evidence to justify the uneasiness of the universities, if not also of the University Grants Committee, particularly in the absence of effective action to remedy weaknesses in the old arrangements which persist into the new.

It is only too clear that the warning addressed by Dr. Haskins to the United States could apply to many other countries. It is quite possible—some might suggest it is already happening—for the fabric of science to be subtly distorted over the long term by public support unwisely or improperly administered, by the lavish granting of funds for this and the withholding of funds for that, on the judgment of a collective patron insufficiently knowledgeable or politically biased. Equally serious is the real danger that any long persistence of such a situation could corrode the inner structure of science by presenting a strong and lasting temptation to disregard scholarly and objective standards, or at least to lower them. Such a situation could cause science to hold out to its public patron arresting technical prospects and thereby acquire additional means to conduct some of the supporting research, or even to add a whole sector of undirected scientific research that could not otherwise have been undertaken.

Dr. Haskins believes that there are contemporary examples of this situation and that it can threaten the very essence of the scientific way itself. It can favour in practice the effective promoter, whose primary value may be the conventional and tired goal of operation for its own sake, over the investigator whose efforts and attention are more deeply committed to winning new knowledge. Even worse, it can further compromise the future by playing on, and thus deepening, the confusion between scientific and technical processes and goals.

Such circumstances give, in Britain, special force to the recommendation of the Parliamentary and Scientific Committee to the Select Committee on Procedure that a new select committee should be set up to examine the annual reports of the Research Councils, the Atomic Energy Authority and other similar bodies and also such scientific and technological matters as were under consideration in Government Departments as a basis for legislation and formulation of policy. The Select Committee on Procedure, in its fourth report last July, embodied this proposal in a wider one which was not very favourably received for the Government by the Lord President of the Council. Nevertheless, the proposal is important and deserves further consideration. Examination in this way of the annual reports of the Research Councils, for example, could well contribute to informed public discussion on the balance of Britain's research effort. It could equally bring to light departmental shortcomings, and it is clear from recent reports from the Estimates Committee that select committees do not regard with favour a tendency to put administrative or departmental convenience before the public interest. The lukewarm reception of the proposal by the Government should be a further reason for its sympathetic and immediate examination.

Dr. Haskins's warning is thus one to be heeded seriously in Britain. It is a part of the problem of the communication of ideas, of the emerging science of science. No doubt, it will be noted by Prof. Blackett and his colleagues in the Royal Society in considering what part that Society should play in the future in the mechanism of scientific advice and in determining the balance of Britain's scientific effort. But the debate must range wider, and the very reluctance of the Ministry of Technology and of the Department of Education and Science to report on their activities makes public debate the more imperative, both within and outside Parliament. The recent plea of the Chairman of the Parliamentary and Scientific Committee deserves the strongest support for the reasons which are so lucidly displayed in Dr. Haskins's review.

A STRAND OF ACADEMIC HISTORY

300 Jahre Physik und Astronomie an der Kieler Universität

Von Charlotte Schmidt-Schönbeck. Pp. 261. (Kiel: Verlag Ferdinand Hirt, 1965.) 15 D.M.

THE University of Kiel was founded in 1665 as part of the reconstruction after the Thirty Years' War and was initially intended for the training of clergy and state officials. During its first hundred years its expansion was checked by dependence on the resources of an impoverished duchy; thereafter it flourished for a century under Danish rule until 1863, when it passed, with Schleswig-Holstein, to Prussia. Under the German Empire the University enjoyed its heyday and scientific and medical studies came into prominence. It was devastated during the Second World War, but has since made a remarkable recovery as a national institution.

300 Jahre Physik und Astronomie an der Kieler Universitat traces the fortunes of physical and astronomical studies at Kiel through the past three centuries by presenting a series of brief biographical studies of forty-seven of its most distinguished teachers in these fields. These notices are grouped according to the special sciences and the periods covered, and each section is prefaced with an account of the relevant developments in the wider field

of European science. Introductory to the whole book are a brief history of the University and an outline of the rise of the physical sciences from antiquity through the Middle Ages and up to the point at which Kiel began to play its not inconsiderable part in their further advancement.

It is of particular interest to note the points at which revolutions in scientific thought began to be reflected in the courses of instruction given at this little University. On the physical side, Kiel appears to have lagged behind the advance of European science in general. Founded some twenty years before Newton's *Principia* appeared, the University courses had assigned no secure place to the Copernican theory by 1700, and it was not until about 1800 that they embraced Newtonian physics. However, about the middle of the nineteenth century there was a great advance on this state of affairs when Kiel established links with more progressive German Universities; thereafter, teachers of the calibre of Heinrich Hertz, Max Planck and Hans Geiger were attracted. The twentieth century brought financial stringency and political persecution, but now, once again, the omens for this historic academy seem favourable.

During the seventeenth and eighteenth centuries, no sharp distinction was drawn at Kiel between physics and astronomy. In the mid-nineteenth century, however, the two sciences drew apart following the foundation of the Kiel Observatory and the creation of various physical institutes. Thereafter, the progress of these two disciplines receives separate treatment in Dr. Schmidt-Schönbeck's pages. The Observatory was completed in 1876, though equipped at first only with old instruments brought from the disused observatory of Altona. Under its first director, C. A. F. Peters, the resources of the new institution were chiefly applied to the time-honoured problems of positional astronomy—the precise determination and cataloguing of star places and motions—while contributing also, latterly through the labours of Elis Strömgren, to the refinement of planetary and cometary orbits. The publication of the *Astronomische Nachrichten* long remained a responsibility of the Kiel astronomers.

This useful handbook presents an immense amount of information which has hitherto not been available, based on a bibliography occupying thirty-seven pages and illustrated with numerous portraits and pictures of historic instruments and institutions. Though primarily concerned with the fortunes of one provincial 'Hochschule', in one aspect of its work, the book possesses a wider interest, for the developing situation at Kiel was typical of the circumstances encountered by several other small German universities.

A. Armitage

EDUCATIONAL RESEARCH

Innovation and Research in Education

By Michael Young. (Institute of Community Studies.) Pp. viii + 184. (London: Routledge and Kegan Paul, Ltd., 1965.) 35*s*. net.

Student Guidance

By Claude Palmer. (Education Today.) Pp. xvii + 108. (London: Longmans, Green and Co., Ltd., 1965.) 10*s*. net.

Innovation and Research in Education was written by Dr. Young before the report of the Heyworth Committee on Social Studies was published, in order to clear his own mind as to priorities in educational research. Since its publication, however, the Government has announced its decision to establish a Social Science Research Council and Dr. Young has been appointed its chairman. Accordingly, the book derives further interest as an indication of Dr. Young's own attitude towards research in the social sciences in general. It is described by him as an invitation to teachers in schools and in training, as well as to administration, to join in a common endeavour to promote research and innovation in education. He argues that the social sciences will be greatly advanced when the entanglement of the social scientist in society is better understood and that this understanding will be promoted if the social scientist deliberately seeks to become involved in action rather than to keep clear of it. Only by linking innovation and research will the methods of the social sciences be greatly improved. Progress will be made not so much by seeking to copy the natural sciences as by recognizing that the social scientist is closely involved with his material and that the problems he has to examine are proposed by his social environment, by his research community, or by other people. Dr. Young strongly emphasizes the importance of the research worker as a variable in any social research, and he insists that, without recognizing the interaction of the research worker and his material, there can be no growth in precision. Unless research workers are more precise, they will not know the grounds of disagreement, and unless disagreement between workers is reduced there can be no cumulative advance of the kind the social sciences need if they are ever to match the progress of the natural sciences. On this view, the most important initial task is to endeavour, with the help of control groups, to measure the effect of observation on its field and that here the vital question is of method.

Dr. Young believes that education offers the greatest scope for advance along these lines in social science research, and points to the closer co-operation between people with different kinds of training which would be generated by experiments along the lines that he suggests. In successive chapters he thus considers the influence of fashion in research, the problems presented by innovation in the classroom, by families and pupils, and in co-operation between home and school. In his final two chapters he discusses methods of research and the organization of research in education. Appendixes are provided describing the extent of research in Departments and Institutes of Education, the organization of educational research in the U.S.S.R., by Dr. W. D. Wall, and finally S. S. Dunn assesses educational research in the light of Australian experience. Apart from an unhappy opening sentence, the book is well written and Dr. Young argues his case clearly and cogently; education, he maintains, needs innovation more than it needs research, and he points out that all-important social changes are made on inadequate evidence and probably always will be. He considers the possibilities of innovation in examinations as well as in the classroom itself, and in co-operation between home and school. In educational research, he concludes that, in the near future at any rate, progress is most likely to be made by setting up some experimental schools and by backing small-scale research run by teachers and research workers in co-operation. He maintains that the Social Science Research Council, which he takes for granted, should be concerned with rather more fundamental research into education, while the Department of Education should be concerned more with the applied aspects. No organization, however efficient, will itself produce research of first quality; that depends, he reminds us, not on committees but on people with a sense of commitment and with a flair for choosing the most hopeful pathway into a problem. He does not overplay the administrator and his hope is that a more scientific approach to education will do something to make it more human. Dr. Young's criticisms are searching but they are fair and open-minded, and the tone of the book, for all its uncomfortableness, is healthy and refreshing.

Minor support for Dr. Young's argument is forthcoming from Mr. Palmer's book, which gives a detailed account of his experience as student adviser at the Barnet College of Further Education. It goes to the root of many student failures and provides convincing evidence that if students are to do themselves justice in further education some

form of student guidance must be an integral part of our educational system in the foreseeable future; it will remain an important element in our social services for young people so long as adolescence remains a time of increasing strain and difficult decisions. The value of such an appointment is fully demonstrated, on the grounds of its contribution to student welfare, to improving their intellectual efficiency, and thus adding to the amount of the talent available to the nation as a whole—and to minimizing the diversion of ability into anti-social channels. In the long run, it offers a saving in time and emotional strain to other members of the staff which it affects, improving teaching and making education in these colleges more efficient, which, in the terms of results achieved, more than repays the financial outlay. *Student Guidance* provides an example of exactly the kind of innovation desiderated by Dr. Young, but Mr. Palmer also pleads for a great expansion of research in all fields of education with as much freedom as possible for the research workers. Likewise, he emphasizes the importance of some independent sources of finance. Some of Mr. Palmer's observations are provocative, and he reminds us that teachers and administrators and many employers can all be a source of frustration. Emphasizing the importance of the teaching of English—failure to master which he regards as an integral part of the overall failure of the student to cope with his or her environment—he observes that we are wasting the talents of thousands of our bright boys and girls, young men and women, for just this neglect. Here he comes near to echoing Dr. Young's own remark that teachers need to concentrate on their proper function of encouraging the desire to learn. In his open-mindedness, he also comes near to reaffirming Dr. Young's further remark that research on the raising of the school-leaving age and what is involved is unlikely to go far if the investigators are already firmly convinced that the extra year is in itself a good thing, or at the least can do no harm. For such open-mindedness, as is shown by these remarks alone, both books are timely and stimulating.

R. BRIGHTMAN

MOLECULAR GENETICS

The Evolution of Genetics

By Arnold W. Ravin. (Academic Paperbacks.) Pp. x+216. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 22*s*. 9*d*.; 2.95 dollars.

IN one way *The Evolution of Genetics* is an excellent book, in another it is depressing. The trouble arises from its title, which leads one to expect some cogent illustration of the way in which contemporary genetics has evolved, an expectation to which the author adds when he complains in his preface that "the debt of modern genetics to the past is easily overlooked".

Yet with what are we presented? 32 pages on the legacy of classical genetics, 147 pages on modern molecular genetics, and 23 pages on the future of genetics. In these first 32 pages we have as the main legacy of classical genetics the concept of a unit of inheritance—the gene (Mendel); the concept of relation between genes and metabolic blocks (Garrod); the concept that genes are chromosomal (Sutton); linkage (Morgan); proof of chromosome exchange in crossing-over (Stern); the origin of theoretical population genetics (Hardy–Weinberg; Fisher, Haldane, Wright); and proof that the cytoplasm counts too (anon).

In the rest of the book we find that, prior to 1940, Griffith had discovered transformation and Muller and Stadler had discovered the mutagenic effects of radiation. Furthermore, and here we come to the crux, we are told (p. 87) that "The very power of the microbial system led to a breakdown of one of the tacit assumptions of classical genetics. The gene, it had been presumed, was a unit of the genetical material that functioned as a single entity in controlling some phenotypic character and responded as a whole to mutation and to recombination". "It was Seymour Benzer who brought this conclusion emphatically home" using phage.

Opinions of which were the key points that led to the opening up of molecular genetics may vary; but none could omit any of the following. The introduction of micro-organisms to genetics by Dodge and Lindegren and to biochemical genetics by Beadle and Tatum; the demonstration by Avery that the transforming factor is DNA; the production of a genetically intelligible structure for DNA by Watson and Crick; and—the point which the author rightly describes as basic—the discovery that genes defined as segregational units, as recombinational units, as mutational units and as physiological units are not necessarily coextensive. But this discovery did not depend on micro-organisms. Well before Benzer's work began, Fisher, Goldschmidt, Darlington, and Mather, among others, were aware that different definitions of the gene were not synonymous, and the demonstration that physiological units were complexes that could be broken down by recombination was made primarily with *Drosophila* (Lewis, Pontecorvo). To say this is not to minimize Benzer's contribution. It is merely to contradict the central point in this account of the evolution of genetics.

As an account of contemporary molecular genetics, the book is simple, straightforward, well written, and has much to recommend it, and the concluding section is a thoughtful account of the views of the author of the problems geneticists must face in the future. It is a pity the author, in his title and preface, should have suggested he was trying to show how molecular genetics arose, a task which, had it been well done, would have been very well worth doing.

J. M. THODAY

A MOLECULAR BASIS OF EVOLUTION

Evolving Genes and Proteins

Edited by Vernon Bryson and Henry J. Vogel. (A Symposium held at the Institute of Microbiology of Rutgers, The State University, with support from the National Science Foundation.) Pp. xxi+629. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 156*s*.

THIS well-presented though expensive volume makes available a detailed account of the proceedings of a symposium held at Rutgers University in September 1964. An impressive array of scientists delivered papers which are collected into nine parts, eight of which begin with a chairman's introductory remarks and which end with open discussion. There are two parts dealing with the evolution of biochemical pathways and three each with the evolution of proteins and genes.

Dedicated to the late D. M. Bonner, *Evolving Genes and Proteins* starts with a list of participants, a short preface by the editors, and a welcome by J. O. Lampen. At the end of the book there is a complete author index and a sensible subject index.

An opening address was delivered by E. L. Tatum, who attempted to place the present knowledge about the molecular basis of evolution in perspective within the framework of the rapidly developing discipline of molecular biology.

In the first section, N. H. Horowitz surveyed the evolution of biochemical syntheses. He proposed a process of retro-evolution whereby evolution started with an end-product of a biosynthetic pathway and worked backward stepwise towards the beginning of the reaction

chain. Thus the first enzyme should carry a memory of its origin. Next H. J. Vogel showed how a biochemical characteristic such as the lysine pathway could be useful to observe evolutionary relationships among a variety of lower organisms.

Part 2 started with K. Bloch's discussion of the evolutionary patterns observed in an examination of the lipids from a variety of organisms. S. Granick then proposed how the biosynthetic chains involved in respiratory and photosynthetic functions developed to produce haem and chlorophyll. He also described the recent evolution of a haem oxidative enzyme and its controls when animals progressed on to land.

The first section on the evolution of proteins began with a long description of evolutionary divergence and convergence in proteins by E. Zuckerkandl and L. Pauling. They assumed that the most important thing to do in the life sciences is to uncover the molecular mechanisms which underlie the observations of classical biology. Next, J. Buettner-Janusch and R. L. Hill discussed the interplay between molecular and organismal aspects of evolutionary events through an investigation of the haemoglobin of man and his primate relatives. Indeed, the differences and similarities among primate haemoglobins reflect to a great extent present ideas of phylogeny. Finally, in this section, G. Braunitzer and his colleagues surveyed amino-acid composition and sequence data of selected respiratory and viral proteins.

The first two papers in the second section on proteins dealt with the structural and functional aspects of proteins presumed to be biologically ubiquitous. Thus phosphoglucomutase and cytochrome *c* were studied by P. Handler's group and E. Margoliash and E. L. Smith respectively in the hope of identifying a protein which is the expression of a homologous gene, thereby exemplifying the common ancestry of life on this planet. N. O. Kaplan then described methods whereby structural and functional relationships among dehydrogenases from different organisms can be compared. He showed that there has been little or no evolutionary change in the structure of coenzymes and discussed the significance of alterations in enzymes. The final paper of this section by W. J. Rutter analysed the molecular features of functionally related proteins derived from various biological sources to provide evidence for the interpretation of basic evolutionary mechanisms.

P. H. Abelson, in his introduction to the final section on proteins, gave an example in which phylogeny based only on protein structure yielded a pattern clearly inconsistent with the taxonomy of the zoologist. The results of detailed studies in the laboratory of the late D. M. Bonner on the tryptophan synthetase systems from *E. coli* and *N. crassa* supported the proposal that the interaction between catalytic units might be followed by conversion to single polypeptide systems. The next paper described work in W. D. McElroy's laboratory and compared luciferase preparations from various species of firefly. E. Freese and A. Yoshida then reviewed the role of mutations in evolution and suggested that rules concerning the preferred types of spontaneous mutations can be used to deduce the nucleotide sequences of normal and mutant genes from the amino-acid sequences of the corresponding proteins. After a summary by S. E. Luria of the evolution of the lactose utilization gene system in enteric bacteria, the final paper in this section was delivered by S. W. Fox. He described *in vitro* experiments which suggest that proteins evolved before cells and genes.

An evening lecture by T. M. Sonneborn on the degeneracy of the genetic code has been expanded for inclusion in this volume. He proposed that natural selection should operate to minimize nonsense and maximize sense.

Part 7, the first section on the evolution of genes, began with a survey of the synthesis of polydeoxynucleotides by A. Kornberg, who suggested that a reiterative copying process might operate occasionally *in vivo* with reference to the natural evolution of DNA. Next E. K. F. Bautz pointed out that RNA species with no coding function have fixed nucleotide compositions whereas those with coding properties can exhibit extensive variations as reflexions of the DNA's characteristic of particular organisms. Using data from analytical studies of *m*RNA made on *T4* DNA as template, he was able to make the much anticipated but important observation that *in vitro* replication and *in vivo* transcription have the same polarity. Finally, in this section, J. Marmur's group described defective bacteriophage particles found in *B. subtilis* and suggested that such particles might represent an evolutionary stage close to temperate phages.

A. Rich started the following section on genes by surveying the details available about the mechanism of protein synthesis. With reference to the evolutionary history of the protein synthesizing mechanism, he envisaged an early stage when the genetic code was not universal. H. Harris then reported on the nature of the short-lived RNA of the cell nucleus. He thought that most of the messenger type RNA produced in the cell was quickly degraded but occasionally mutations occur in the unstable *m*RNA conferring stability on it, thus allowing it to function in the cytoplasm should it produce an evolutionary desirable protein. To close this session N. Sueoka discussed the evolution of informational macromolecules. He also suggested that the accepted scheme for the translatory mechanism was established before the ramification of organisms.

M. Demerec commenced the final session and concluded that genes might be homologous with respect to their function yet differ in their molecular structure. Next, V. Moses and M. Calvin discussed the possible evolutionary significance of molecular regulation with particular reference to the consequences of differential *m*RNA stability. Studies of the relation of *r*RNA to the genome carried out by S. Spiegelman and S. A. Yankovsky are reported in detail. They concluded that a multiplicity of cistrons exists for *r*RNA and also located *Drosophila* DNA complementary with *r*RNA in the region of the nucleolar organizer. The work of R. B. Roberts and his colleagues was discussed with reference to the evolution of polynucleotides. Finally, the symposium ended with R. Sager pursuing the possible paths of the evolution of genetic material from the consideration of work on the recombination of non-chromosomal genes.

Clearly the mass of data collected together in this volume makes it a necessity for specialists in this field and provides a background for those wishing to enter the field. It will be readily understood by graduates trained in biochemistry. Because of the range of articles, which includes reviews and the presentation of new results, I have commented only on what I consider to be the more interesting points made by the various speakers. No modern library for biological chemistry should be without it.

B. F. C. Clark

SENSORY DEPRIVATION

Inside the Black Room

By Dr. Jack A. Vernon. Pp. xvii + 203. (London: Souvenir Press, Ltd., 1965.) 21*s*. net.

INSIDE the Black Room is an attempt to give a popular account of the work done on sensory deprivation by a number of research workers at Princeton, and was first published in the United States in 1963. The project was made possible by grants from the Office of the Surgeon General of the U.S. Army and from the National Science Foundation, and the type of research followed was that previously initiated by Dr. D. O. Hebb and his associates, working at McGill University, where the term 'black box' was first incorrectly used to indicate the room in which the experiments were conducted. At McGill

the cubicle in which the subjects were confined was lighted but rendered semi-soundproof: at Princeton the room was lightproof and soundproof.

Examination of the effects of sensory deprivation was originally intended to throw light on the reduction of variability and quantity of sensory stimuli as a potential hazard in space flight, but even before these experiments unusual sensory effects had been recorded with radar observers and other workers engaged in very monotonous and routine jobs. As observations multiplied, so the whole subject became connected with what was called 'brain-washing' and this was the main point dealt with by the experiments at McGill.

Dr. Vernon's arrangements were more severe than those of Dr. Hebb, although both used only male subjects, those assisting Vernon being about one hundred Princeton graduates aged between twenty and thirty-two. Confinement was usually continued up to ninety-six hours, although the subject could obtain release at any time should he find the situation intolerable by pressing a button, although no continuation of the test was permitted once he had left the cubicle. The usual arrangements were made for providing food and toilet facilities.

As a result of the experiments a number of facts relating to conditions of sensory deprivation were found. About one out of five subjects used the release button before their time was up; and although they were forbidden to smoke they found to their surprise that they no longer wanted to do so. It was found that, using the body-sway test, suggestibility could be increased and the under-estimation of time was a marked characteristic. Effects on thinking varied: in some cases it remained clear, but for most subjects connected thought became weaker the longer confinement was continued.

As regards physical effects, it was found that confinement had an undesirable effect on some simple motor tasks, although no effect on reaction time was observed. Sensitivity to pain was increased, and what was more unexpected was a loss of weight due to the fact that the subjects did not consume enough to prevent it.

Dr. Vernon's study is a clear and interesting exposition of the general effects of sensory deprivation under certain well-defined conditions. But what is now clear is that much more work will have to be done, including tests with less educated and with female subjects and with persons of widely differing age groups. It seems that man does not well endure such conditions, since they afford no variation in the few stimuli presented to him. Even the simplest stimulus is received with pleasure and becomes a subject for study. If the results of sensory deprivation are to be accepted, then the dependence of modern man on the external world and the limitations of his own self-sufficiency have been exemplified. E. J. DINGWALL

PARASITES OF FRESHWATER FISH

Key to Parasites of Freshwater Fish of the U.S.S.R.

Compiled by I. E. Bykhovskaya-Pavlovskaya *et al.* Translated from the Russian. Pp. viii + 919. (Jerusalem : Israel Program for Scientific Translations; London: Oldbourne Press, 1964.) 180*s*.

KEY to Parasites of Freshwater Fish of the U.S.S.R. was originally published in 1962. The book contains keys to the identification of 1,211 species of parasites from freshwater fish of the U.S.S.R. The parasites belong to seven phyla and fifteen classes of invertebrates. The keys are constructed on a dichotomous pattern, and require comparisons of characters of the parasite to be made. A description of each species of parasite is given.

The Protozoa occupy 231 pages of the translation; the Coelenterata, 2 pages; the Platyhelminthes Monogenoidea, 207 pages; Cestoidea, 66 pages; Trematoda (Digenea), 104 pages; the Nemathelminthes Nematoda, 67 pages; Acanthocephala, 45 pages; the Annelida Hirudinea, 13 pages; the Mollusca, 4 pages; the Arthropoda Crustacea, 57 pages; and Arachnoidea, 5 pages. There is a twelve-page index of common and Latin names of the fish, followed by a thirty-nine-page list of parasites of the freshwater fish of the U.S.S.R., arranged under species of host. The bibliography gives references to 249 Russian and 116 foreign (non-Russian) publications. A list entitled "Basic Manuals, Keys and Papers on Fish Parasites" contains thirty titles, all by non-Russian authors.

The index of Latin names of the parasites is photographically reproduced from the original publication and occupies the final thirty-three pages of the book. Unfortunately, the page numbers of the original book are given, and although these are shown at the margins of the text of the translation, the index is inconvenient to use at first. Thus the text of p. 665 of the Russian original appears on pp. 784 and 785 of the translation.

According to the introduction, the book is for the use of persons of biological background who are not necessarily parasitologists. Each section commences with an introduction which describes the morphology, biology, phylogeny and epizootological significance of the parasites being considered. This is an excellent feature, but I am doubtful if a person inexperienced in the study of some of the groups of parasites would be able to find and correctly interpret some of the structures. It is strongly recommended that identifications made by inexperienced workers be referred to an expert for confirmation. This comment is not intended to condemn the selection of key characters, or the construction of the keys. It is a warning that identification is not necessarily an easy process, and that incorrect determinations can be easily made no matter how good the keys.

The descriptions given for each species of parasite are brief and to the point. The illustrations are largely from the world literature, although some are original. On the whole they are good, but some have suffered in quality owing to their manner of reproduction in the translation.

The book is a key to the parasites of the fishes of the U.S.S.R., and species not found in the U.S.S.R. are omitted. This is an obvious point, but, as the translation will be used outside the U.S.S.R., it is an important one. If the keys do not work for a parasite, it must be remembered that it may be a species not recorded from the U.S.S.R.

The translation from the Russian appears to be accurate. A comparison of the part of the book dealing with the class Cestoidea was made with a translation of the same part prepared by the Translations Section of the National Lending Library[1]. The comparison was favourable, as the two translations were identical in factual content and interpretation of the Russian original.

The editor and authors of the original publication are to be congratulated on the excellent compilation. As they point out in the foreword, the authors are under no illusion that the work is complete, or free from deficiencies. They invite critical remarks and supplementary material for incorporation in future editions. The translators should also be complimented on the production of the English version in the relatively short time since the appearance of the original.

While not everyone will agree with the taxonomic treatment given to some of the groups of parasites, this in no way affects the value of the book as a key-work. The book is highly recommended, and should be an invaluable aid to the identification of freshwater fish parasites. The keys were tested with a variety of parasites from several groups, and the correct identifications achieved. JAMES C. CHUBB

[1] Dubinina, M. N., *Class–Tapeworms*. Translation of pp 384-438 Opredelitel Parazitov Presnovodnich Rib S S S R. Akad. Nauk S S.S.R Moscow-Leningrad (National Lending Library for Science and Technology, December, 1964)

The Works of William Harvey, M.D.

Translated from the Latin with a Life of the Author by Robert Willis. (The Sources of Science, No. 13.) Pp. xcvi+624. (New York and London: Johnson Reprint Corporation, 1965.) 25 dollars.

THE Johnson Reprint Corporation are publishers of an excellent series, "The Sources of Science", in which they reprint the original work of pioneers, such as Boyle, Newton, Kepler and Grew. This compendious volume contains the works of William Harvey; a reprint of *De Motu Cordis*, *De Circulatione Sanguinis* and *De Generatione Animalium*, which were prepared for the Sydenham Society by Robert Willis and published in 1847. Willis also included some of Harvey's letters to foreign medical correspondents, the report on Thomas Parr, a transcript of Harvey's will and a memoir of Harvey.

Robert Willis, M.D. Edinburgh, was Librarian of the Royal College of Surgeons from 1828 to 1845. After this he was in general practice at Barnes. A good linguist, he translated Wagner's *Physiology* from the German and *Rayer on Skin Diseases* from the French. He died in 1878.

Willis had had a classical education, and his translations of Harvey's works were an improvement on those of previous translators. Harvey wrote excellent Latin, *pace* Aubrey, but his English translators, including Willis, are not sufficiently accurate for those doing either historical or experimental research. Willis's translations of *De Motu Cordis* and *De Circulatione Sanguinis* have been superseded by the scholarly translations of Prof. Kenneth J. Franklin (now obtainable in the Everyman edition). Prof. Franklin has exceptional gifts for translating the works of Harvey, being a physiologist, classical scholar and medical historian. This reprint of Willis's English translation is, therefore, chiefly of historic interest, although until Prof. Franklin's translation is published it is the best available of *De Generatione*.

ARTHUR MACNALTY

Le Message Héréditaire

Par Jean de Grouchy. Pp. xi+196. (Paris: Gauthier-Villars, 1965.) 26 francs.

IN the past ten years molecular genetics has advanced in a spectacular way, and several people have felt the urge to communicate these developments to a wider public. There has been a spate of books written at various levels which should ensure that the present generation of sixth formers and undergraduates can easily assimilate the major developments. Even the youngest of the masters, James Watson, has recently given us a stimulating and informative summary, *The Molecular Biology of the Gene*.

Le Message Héréditaire is written at an intermediate level, suitable for students in general biology, and—with its several examples from human disorders—for medical students. It follows the general pattern set by Dr. de Grouchy in 1958 with his *L'Hérédité Moleculaire*. Comparison of the two books is instructive because it reminds us how radically views have changed during the past seven years. During this time the roles of transfer-RNA, messenger-RNA, polyribosomes, enzymatic transcription and coding have all been clarified, and a beginning has been made in the analysis of mechanisms controlling expression of genes. Dr. de Grouchy conveys his message with simplicity and clarity, quoting most of the classical examples from microbial and human genetics. Even controversial subjects such as control mechanisms are handled tactfully. The Jacob–Monod system is fully presented, but some recent microbiological evidence which has led to conclusions at variance with the Parisian orthodoxy are mentioned. Suggestions that a number of human disorders are due to abnormalities of control mechanisms are quoted, even though one does not, unfortunately, know in any single case whether this is the correct explanation of the observations.

The material is adequately illustrated and systematically presented, so the absence of an index is no great handicap. The book is accurate and well written, and it will doubtless be widely read by French students; but the language barrier, and the fact that excellent alternatives are available in English, will probably limit its use in Britain and the United States.

A. C. ALLISON

Outline of Endocrine Gland Syndromes

By Prof. T. S. Danowski. Pp. ix+374. (Baltimore: The Williams and Wilkins Company, 1965. Distributed in the U.K. by E. and S. Livingstone, Ltd., Edinburgh.) 50*s*. net.

OUTLINE of Endocrine Gland Syndromes provides a synopsis of present knowledge regarding the aetiology, clinical features, differential diagnosis, prognosis and therapy of endocrine diseases with the exception of diabetes mellitus which is discussed in a companion volume. Although the style of writing is in places somewhat cryptic, most of the relevant information is presented, the sections dealing with the thyroid, parathyroids and adrenal cortex being more comprehensive than those concerned with the anterior and posterior pituitary and the gonads. The bibliography on purely clinical topics is generally adequate and includes many recent references. However, the value of hormone assay procedures in the diagnosis and management of endocrine diseases is not greatly emphasized, and it is to be hoped that in later editions of the volume this aspect of the subject will be expanded. The book in its present form should prove valuable not only to the clinical endocrinologist but also to the general physician who is anxious to acquaint himself with recent developments in this speciality.

JOHN A. LORAINE

Bibliography of Statistical Literature

1940–1949. By Dr. Maurice G. Kendall and Alison G. Doig. Pp. 190. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 55*s*.

THIS is the second volume to appear of the projected three-volume bibliography which is intended to provide a complete bibliography of statistical literature from its earliest beginnings until 1958, when the *International Journal of Abstracts of Statistical Theory and Method* commenced its coverage. The volume for the period 1950–58 appeared in 1962, and will already be familiar to many statisticians. The high standard set by this earlier volume has been maintained. In each volume papers are listed alphabetically by the name of the author followed by the title and exact journal reference.

Since there is at present no indexing by subject, the bibliography as it stands is of little direct use to the statistician, but the availability of this almost exhaustive list of statistical articles will make it easy to compile specialized bibliographies for any particular purpose. There is also a reasonable hope that a subject index, such as that already prepared by M. J. R. Healy (described in the *Journal of the Royal Statistical Society*, series A, 126, 270; 1963), will eventually be published. The work is therefore likely to gain in value as time passes.

A serious defect of the work is that quite a high proportion of the titles in foreign languages are not translated into English, although in some cases a French or German translation is given. It is often fairly easy to guess the meaning of those in Portuguese or Italian, but occasional Swedish titles, for example, may be completely baffling. No doubt the authors, with inadequate resources and limited time, have done far better than could reasonably be expected. The fault lies rather with the authorities who failed to provide assistance when it would have done most good.

D. F. KERRIDGE

ON THE NATURE OF THE QUASI-STELLAR SOURCES

By Prof. F. HOYLE, F.R.S.
University of Cambridge, and California Institute of Technology
AND
Prof. G. R. BURBIDGE and Prof. W. L. W. SARGENT
University of California, San Diego

In a recent paper, under the same title as this article[1], two of us have discussed both the usual cosmological interpretation of the red-shifts of the spectrum lines of the quasi-stellar objects and also the possibility that these objects are comparatively 'local' to our Galaxy, with distances of 1–10 Mpc. The work was begun with the conventional prejudice toward the cosmological interpretation, the initial aim being to disprove the local hypothesis. In the outcome, however, we were not able to satisfy ourselves that the local hypothesis must be discarded—in fact we arrived at a balanced position between the two hypotheses. In this communication we do not propose to repeat the former arguments but to put forward new considerations which seem to us to point toward the local hypothesis.

The new argument turns on the Compton process in which relativistic electrons are inelastically scattered by low-energy photons. The importance of this process was realized by Greenstein and Schmidt[2] and also discussed by Ginzburg, Ozernoi and Syrovatsky[3]. Like synchrotron radiation, the Compton process depends on the presence of electrons of relativistic energies. The electrons lose energy by the synchrotron process and by the Compton process in accordance with the ratio:

$$\frac{\text{Loss by Compton scattering}}{\text{Loss by synchrotron scattering}} = \frac{U_{\text{rad}}}{H^2/4\pi} \qquad (1)$$

where U_{rad} is the energy density of the radiation field. In order to apply the relation (1) to the Compton process it is necessary to discuss two important questions: (*a*) What is the intensity of the synchrotron emission from quasi-stellar objects? (*b*) What are the dimensions of the emission regions? We begin with a discussion of (*a*).

The observed radiation from quasi-stellar objects is thought to be derived from two processes: (i) synchrotron radiation and (ii) radiative recombination of an ionized gas. The most detailed studies have been carried out for 3*C* 273 and 3*C* 48. There is no question but that the radio frequency radiation from the quasi-stellar objects is generated entirely by the synchrotron process. However, as will become clear from the later discussion, it is the high-energy density of radiation which comes almost entirely from the flux emitted in the optical and infra-red spectrum which is of critical importance here.

Matthews and Sandage[4] ascribed the whole of the continuous radiation from 3*C* 48 in the wave-length range $3{\cdot}0$–$8{\cdot}3 \times 10^{14}$ c/s to the synchrotron process. Greenstein and Schmidt[2] and Oke[5] have both discussed the optical spectrum of 3*C* 273 in terms of radiative recombination of a hot gas. In Fig. 1 we compare the observed continuous energy distribution in the optical and near-infra-red regions published by Oke and by Johnson[6] with the theoretical radiative recombination spectra of the two models discussed. The two theoretical spectra have been given an arbitrary vertical shift to facilitate comparison of the forms of the continua.

Oke chose a value of $T_e = 160{,}000°$, which gives the observed Balmer discontinuity, *B*; however, the Paschen continuum must then be ascribed to a component of unknown origin (which Oke supposed to be synchrotron radiation) which rises steeply into the near infra-red. As Oke pointed out, Greenstein and Schmidt's model with $T_e = 16{,}000°$ requires Balmer and Paschen discontinuities much larger than those observed; thus in their case also a spectrum rising steeply into the infra-red must be added to the recombination spectrum. Searle *et al.*[7] have shown that in each case the spectrum which must be added has the same slope as those of the Crab nebula and 3*C* 48. This is very strong evidence that the near infra-red continuum of 3*C* 273*B* is dominated by synchrotron radiation; Dibai and Pronik[8] have also given strong arguments for this conclusion. The presence of a small Balmer discontinuity together with the Balmer emission lines shows that a hydrogen recombination spectrum is also present and begins to dominate below λ4,000.

Extension of the observations of 3*C* 273 into the infra-red ($\nu = 3 \times 10^{13}$–$1{\cdot}4 \times 10^{14}$ c/s) by Johnson and Low[9] and into the millimetre range ($\nu = 10^{11}$–3×10^{11} c/s) by Low[10] and Epstein[11] has shown that this object is an exceedingly powerful emitter in these regions. For other quasi-stellar objects there are no published observations of fluxes in the infra-red, but indications that the fluxes are rising in the near infra-red suggest (because of the effect of the red-shift) that a synchrotron contribution may be important in the optical region in some objects.

An integration of the energy distribution curve of 3*C* 273 shows that the total flux received at the Earth in the frequency range 10^{11}–5×10^{14} c/s is $5{\cdot}3 \times 10^{-9}$ erg/cm²/

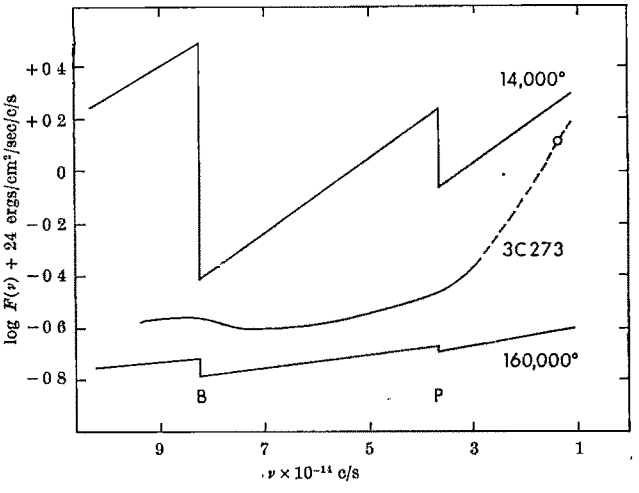

Fig 1. The continuous energy distribution of 3*C* 273 in the optical and near infra-red is compared with the theoretical hydrogen recombination continua appropriate to electron temperatures of 14,000° and 160,000° given by Oke (ref. 5). The continuous line represents Oke's observations of 3*C* 273. The circle represents Johnson's (ref. 6) measurement of the flux at 2·2μ. The ordinate is the logarithm of the observed flux per unit frequency interval from 3*C* 273 at the Earth's surface. The units are 10^{-24} ergs cm^{-2} sec^{-1} (c/s)$^{-1}$. The abscissa is the frequency in units of 10^{14} c/s. Note that the theoretical continua have been given arbitrary vertical shifts

sec. The bulk of this radiation is emitted in the frequency range 10^{11}–10^{13} c/s. For 3*C* 48, Sandage[12] obtained a flux of $1{\cdot}1 \times 10^{-11}$ erg/cm²/sec for this frequency range.

It has often been pointed out that detection of a significant degree of polarization in the radiation might add weight to the circumstantial evidence for the flux being synchrotron radiation. In the case of 3*C* 48, Hiltner found that the degree of polarization in the optical region is less than 2 per cent. Recently, Schmidt[13] has reported that in 3*C* 273*B* there is no measurable polarization in the frequencies near $7{\cdot}5 \times 10^{14}$ c/s, but at 6×10^{14} c/s about 4 per cent polarization is present. This is consistent with a steadily increasing proportion of synchrotron radiation at lower frequencies.

We conclude that the bulk of the energy emitted from 3*C* 273 and probably from the quasi-stellar objects in general is synchrotron radiation. We consider next the dimension of the source from which this radiation is emitted.

It is well known that it is the flux variations from the source which set a much stronger upper limit for the size than the 'quasi-stellar' characteristic. 3*C* 273*B* has been shown to vary in the optical region in time scales of years and months[14]. Recent observations in frequencies near 3×10^{11} c/s (ref. 9) suggest that there have been large variations in periods of months. In other quasi-stellar objects variations in the optical flux of similar and sometimes shorter time scales are seen. In the case of 3*C* 345 significant optical and spectroscopic variations on a time scale of weeks have recently been reported[15,16] though no observations of the infra-red flux in this object are available. Thus a reasonable scale to take for the size of the region in which this synchrotron flux is generated is $\sim 10^{17}$ cm or about a light month.

We return now to our discussion of the inverse Compton process. In attempting to estimate the relative importance of the synchrotron process and the Compton scattering process, we first considered that the dimension of a 'coherent' emission region is such that a relativistic electron can travel in its lifetime across the whole region. For a sphere of radius R this requires $\tau > R/c$, where τ is the electron lifetime against synchrotron radiation. Calculating τ from the synchrotron process alone, we have:

$$\tau = 10^{12}\nu^{-1/2}H^{-3/2} \text{ sec} \qquad (2)$$

where H is the magnetic intensity in gauss and ν is the critical frequency in c/s of the electron in question. From the inequality $\tau > R/c$, we obtain:

$$H^{3/2} < 3 \times 10^{22}\nu^{-1/2}R$$

giving:

$$\frac{H^2}{4\pi} < \sim 10^{29}\nu^{-2/3}R^{-4/3} \qquad (3)$$

R being in cm.

Suppose first that the whole emission comes from just one such coherent region. Then, if d is the distance to the source and s is the flux in ergs cm^{-2} sec^{-1} at the Earth, $L = \pi R^2 c\ U_{\text{rad}} \simeq 4\pi d^2 s$, neglecting a red-shift factor, so that:

$$U_{\text{rad}} \approx \frac{4d^2 s}{R^2 c} \qquad (4)$$

Taking the ratio of (4) to (3):

$$\frac{U_{\text{rad}}}{H^2/4\pi} = \frac{4d^2 s}{10^{29}c}\left(\frac{\nu}{R}\right)^{2/3}$$

If we substitute for s the value of $5{\cdot}3 \times 10^{-9}$ erg/cm²/sec, then:

$$\frac{U_{\text{rad}}}{H^2/4\pi} = 63{\cdot}6\ D^2\left(\frac{\nu}{R}\right)^{2/3} \qquad (5)$$

where D is measured in megaparsecs (Mpc) ($d = 3 \times 10^{24} D$). Putting $D = 470$ Mpc, the cosmological distance for 3*C* 273, we have:

$$\frac{U_{\text{rad}}}{H^2/4\pi} = 1{\cdot}3 \times 10^7\left(\frac{\nu}{R}\right)^{2/3}$$

Thus, if $R = 10^{17}$ cm and $\nu = 10^{14}$ c/s (the near infra-red):

$$\frac{U_{\text{rad}}}{H^2/4\pi} = 1{\cdot}3 \times 10^5 \qquad (6)$$

It is of some interest to apply a similar argument to the case of 3*C* 345. This quasi-stellar source which has a red-shift $z = 0{\cdot}595$ (ref. 17) has varied significantly in a time scale of $\sim$ light week or $\sim 10^6$ sec (ref. 15). In this case we do not have such strong evidence that a major part of the flux is synchrotron radiation. The flux that is seen is ultra-violet radiation and we have no knowledge concerning the flux in the frequency range discussed for 3*C* 273 because of the much larger red-shift. However, we shall assume that the flux is synchrotron in origin. Taking an apparent magnitude of $17^{\text{m}}{\cdot}0$ for 3*C* 345, we find that for this object $s = 8{\cdot}4 \times 10^{-12}$ erg/cm²/sec. Thus for this source, going through the same steps as before:

$$\frac{U_{\text{rad}}}{H^2/4\pi} = 1{\cdot}0 \times 10^{-1}D^3\left(\frac{\nu}{R}\right)^{2/3}$$

The cosmological distance, D, is equal to 1,770 Mpc. and thus:

$$\frac{U_{\text{rad}}}{H^2/4\pi} \approx 3{\cdot}1 \times 10^5\left(\frac{\nu}{R}\right)^{2/3}$$

Putting $\nu = 6 \times 10^{14}$ c/s, $R = 3 \times 10^{16}$ cm:

$$\frac{U_{\text{rad}}}{H^2/4\pi} \approx 2{\cdot}3 \times 10^4 \qquad (7)$$

Thus, provided that the ultra-violet radiation from 3*C* 345 is synchrotron in origin, we arrive at much the same ratio as for 3*C* 273.

The results (6) and (7) give a manifest contradiction because U_{rad} in (6) and (7) was calculated from the synchrotron process alone. Our results would therefore require the energy density of radiation from the Compton process to be greater than that from the synchrotron process by the large factor $\sim 10^5$, yielding a divergence in which the inverse Compton process acts on itself, giving a repeated stepping up of the energies of quanta initially generated by the synchrotron process. When U_{rad} is estimated from the synchrotron process, the right-hand side of (1) must not be greater than unity. It may be noted that this requirement prevents one from arguing that the optical and infra-red emission arises from the Compton process acting on radio-frequency quanta. For, since the energy of the former much exceeds the latter, it would be necessary on this idea for the Compton process to multiply the energy of the synchrotron process by a large factor. The same process would then multiply itself by a similar factor, giving an impossible divergence.

Reference to (4) shows that these difficulties are avoided if the distances of the quasi-stellar objects are reduced by a factor $\sim 10^2$, that is to say, from characteristic distances of 1,000 Mpc to characteristic distances of 10 Mpc. It seems to us rather unlikely that the cosmological interpretation of the distances can be saved by any modification of our argument except perhaps by modifying our assumption that the emission comes from just one coherent region—in the sense we have used coherence (compare equations (2) and (3)). We continue our discussion by examining the consequences of denying this assumption.

Suppose there are n coherent sub-regions each of radius R. Proceeding in the same way as before, but now for a single sub-region, we find that $4\pi U_{\text{rad}}/H^2$ is reduced by n. Evidently, for n large enough this ratio can be reduced to a value of order unity—even when D is a cosmological distance. However, since the fluctuation data require all n sub-regions to be fitted into an overall dimension of $\sim 10^{17}$ cm, it is clear that for $n \gg 1$ the radius R of each region must be taken substantially less than 10^{17} cm. Thus the factor $(\nu/R)^{2/3}$, which appears in the analysis,

cannot now be taken much greater than unity. It follows that n must be still larger than the numerical values appearing in equations (6) and (7)—$n \geqslant \sim 10^6$ is needed.

The problem is then to explain how so many sub-regions can vary in phase with each other, as they must do if their combined radiative output is to vary at all appreciably in a time scale of a few weeks. A correlation between the sub-regions is needed—they cannot be autonomous. We might think of a magnetic field maintaining a connexion from one region to another, but for the connexion to be strong enough to co-phase the regions the magnetic intensity could not be significantly less in the inter-region zone than it is within the regions themselves. The concept of separate sub-regions then becomes of doubtful validity and it seems better to return to a single coherent region of dimension $\sim 10^{17}$ cm. However, we can now regard the 'coherence' as being maintained by a magnetic field rather than by a diffusion from place to place of the relativistic particles. In terms of our previous analysis, we can increase the value of H^2 until the ratio $4\pi U_{rad}/H^2$ falls to unity. The effect of such an increase is to give extremely short lives to the relativistic electrons. Instead of a few weeks, the lifetimes are only $\sim 10^3$ sec—this is for the electrons which radiate the main energy, at $\nu \simeq 10^{14}$ c/s.

It would seem then that the assumption of cosmological distances for the quasi-stellar objects leads to the requirement that relativistic particles are generated *in situ*. From what? Perhaps from oscillations in the magnetic field. In order to explain the optical fluctuation data such oscillations must propagate with essentially the speed of light—the oscillations would need to be electromagnetic, not hydromagnetic.

A mechanism for generating electromagnetic waves has been discussed by Hoyle, Narlikar and Wheeler[18]. The waves were regarded as being emitted in the dynamical oscillations of a highly collapsed star, the wavelength being a few kilometres. Such waves do not propagate unless the electron density is very low. Hence it would be necessary for an inner region of dimension $\sim 10^{17}$ cm surrounding a collapsed object to be largely devoid of matter. To prevent the waves simply radiating freely into space it would also be necessary in such a model to trap the waves within the inner region, by surrounding the region with a gas cloud of comparatively high density. It may be added that the distinction between synchrotron emission and the Compton process is now lost; the two processes are the same in a purely electromagnetic field.

Difficulties remain, however. The most immediate is that the outer gas cloud must have a characteristic dimension of the same order as the radius of the inner region, $\sim 10^{17}$ cm. For a dimension as small as this it is hard to obtain sufficient line emission (for example, for Hβ in 3*C* 273) without requiring the electron density to be so high that the cloud is very opaque in the continuum.

We conclude that either the quasi-stellar objects are at distances of ~ 10 Mpc or less, or the physical model associated with these objects must be substantially different from the theories at present in vogue.

ANGULAR DIAMETERS OF SOME RADIO SOURCES WITH ANOMALOUS HIGH-FREQUENCY SPECTRA

By D. BARBER
Royal Radar Establishment, Malvern
AND
W. DONALDSON, G. K. MILEY and H. SMITH
Nuffield Radio Astronomy Laboratories, Jodrell Bank, Cheshire

DENT and Haddock[1,2] have recently directed attention to the existence of a class of radio sources in which the flux densities at frequencies above 3,000 Mc/s are greater than would be predicted by a linear extrapolation of the low-frequency spectra. Altogether seven such sources are listed in refs. 1 and 2. The present communication discusses the dimensions derived from observations of five of these sources (3*C* 84, 3*C* 273, 3*C* 279, 3*C* 345 and 3*C* 380) using an interferometer of very high resolving power, operating at a frequency of 1,422 Mc/s.

Previous authors[3,4] have discussed a connexion between the angular diameter of a source and the existence of a low-frequency cut-off in the spectrum. The new information on angular sizes presented here seems to indicate that anomalous spectra of the type reported by Dent and Haddock are also associated with sources of extremely small diameter. Interferometric observations were made during May and June 1965 using the Mark I 250-ft. radio telescope at Jodrell Bank and one of the 82-ft. radio telescopes of the Royal Radar Establishment. The Royal Radar Establishment instrument is at Defford, near Malvern, and effective baselines of up to 604,000 wave-lengths were achieved. The equipment has been described by Adgie *et al.*[5], who have also given details of the normalization procedure and calibration of the absolute sensitivity of the system.

Two of the sources (3*C* 273, 3*C* 380) were observed at all hour angles at which they were above the horizon, and a third (3*C* 84) was observed over a large but incomplete range of hour angles. The remaining two sources

(3C 279, 3C 345) could be observed only very briefly because of the limited period during which both telescopes were available for this work. Observations made at elevations less than 15° have not been included in the analysis because of the large correction factors involved[5]. The results of the measurements are summarized in Table 1, which also contains some earlier data for comparison. It can be seen that, for all five sources, the angular dimensions at 1,422 Mc/s are smaller than at the lower frequencies.

Each of the five sources gave a clear fringe pattern at all the hour angles at which it was observed, indicating that in every case a substantial part of the emission comes from a region or regions smaller than 0·1 sec of arc. As reported by Adgie *et al.*, the source 3C 273B shows a dependence of fringe amplitude on hour angle which indicates that it probably contains two such small components. The less intense source 3C 380 also shows some changes in fringe amplitude which are believed to be significant and suggest a more complex structure than that attributed to 3C 273B. More measurements are required in order to confirm this interpretation. The observations of the remaining sources did not reveal any significant changes of fringe amplitude with hour angle. It is not possible, therefore, to derive any detailed information about the angular structure of 3C 84, 3C 279 and 3C 345.

Four of the sources discussed here have been identified with quasi-stellar objects[14,15] and the remaining one (3C 84) with the Seyfert Galaxy *NGC* 1275 (ref. 16). Three of the quasars, 3C 273B, 3C 279 and 3C 345, are known to have variable optical luminosities[17–19]. Variations of radio emission from these three quasars and from 3C 84 have also been observed by Dent[9,20] at both 8·0 and 16·5 Gc/s. Out of thirty-five radio sources which he examined, these four were the only extragalactic sources for which he reported variations in flux density, and it is interesting to note that all four of them appear to have a component smaller than 0·1 sec of arc at 1,422 Mc/s. (The reported radio variability of *CTA* 102 (ref. 21) is still controversial[22].)

A value for the optical red-shift has been published for each source[14,18,23,24]. If it is assumed that the red-shifts are due to the general expansion of the Universe and a particular cosmological model is adopted, the angular size measurements reported here can be used to calculate an upper limit to the linear dimensions of the radio-emitting regions. These linear dimensions, and information on optical and radio variability, are presented in Table 2. Variations on time scales such as these have previously been taken to imply that these sources have components of very small linear dimensions, and a similar conclusion follows from the present observations, even though the

Table 1

3C 380	Quasi-stellar radio source	0 691	⩽350	⩾4·4 × 10⁸	—	—

* Calculated on the assumption of a zero cosmological constant and a deceleration parameter $q_0 = +1$ (ref. 27). If $q_0 = 0$ these values must be multiplied by (1 + 0 5z). Hubble's constant, H, has been taken as 100 km/sec/megaparsec.

† Epoch 1965·5.

observing frequency is lower than those at which variability has generally been observed.

It is apparent that in respect of their unusual radio spectra and variations in flux density the quasars 3*C* 273, 3*C* 279 and 3*C* 345 are remarkably alike. They are also among the small number of radio sources known to have very high brightness temperatures (see Table 2). The radio luminosity of 3*C* 84 is smaller than that of the quasars by two or three orders of magnitude, but with regard to the three radio properties mentioned here, there is a close similarity. These measurements therefore provide support for the views of Shklovskii[28] and Hoyle and Burbidge[29] that similar explosive processes to those in some, presumably young, quasars are occurring in this Seyfert Galaxy. The measurements also support the suggestion of Hoyle and Burbidge[29] that variations in optical brightness may be expected in 3*C* 84. Further, in view of the anomalous spectrum of 3*C* 380 and the high brightness temperature at 1,422 Mc/s, this source might also be expected to show variations in optical and radio brightness. It has so far not shown any radio variations[20], but it would be interesting to extend the search to cover a longer period of time, and to include optical as well as radio wave-lengths.

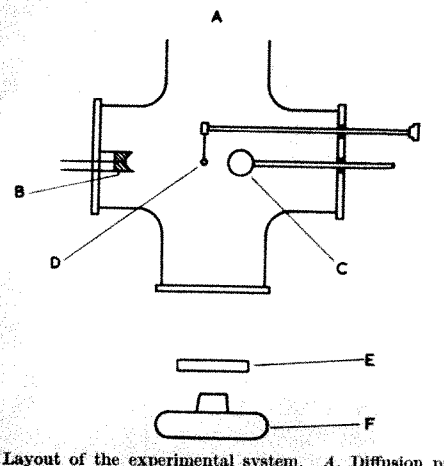
IMPACT OF PLASMA ON A DIPOLE MAGNETIC FIELD

By Dr. J. B. G. ROBERTS and J. P. TURNER

Royal Radar Establishment, Malvern, Worcestershire

THE interaction of the solar corpuscular stream with the Earth's magnetic field has been the subject of many theoretical and experimental investigations; but despite the great volume of data provided by artificial satellites and space probes, the structure of the magnetosphere and the mechanisms producing magnetic storms and aurorae are not yet well understood. Observations from space vehicles do not provide a complete picture of the magnetosphere and it is also difficult to distinguish spatial and temporal variations. In these circumstances a laboratory simulation under controlled conditions can be of considerable value in demonstrating the type of interaction that may occur. In the experiments described here plasma was made to impinge on a dipole magnetic field; and to correspond with the solar wind, the values of the plasma velocity, V, and conductivity, σ, were chosen so that, for a convenient experimental scale length, L, the product $4\pi\sigma LV$ (the magnetic Reynolds number) was much greater than unity. With these conditions, the incident plasma would be expected to compress the field in front of it.



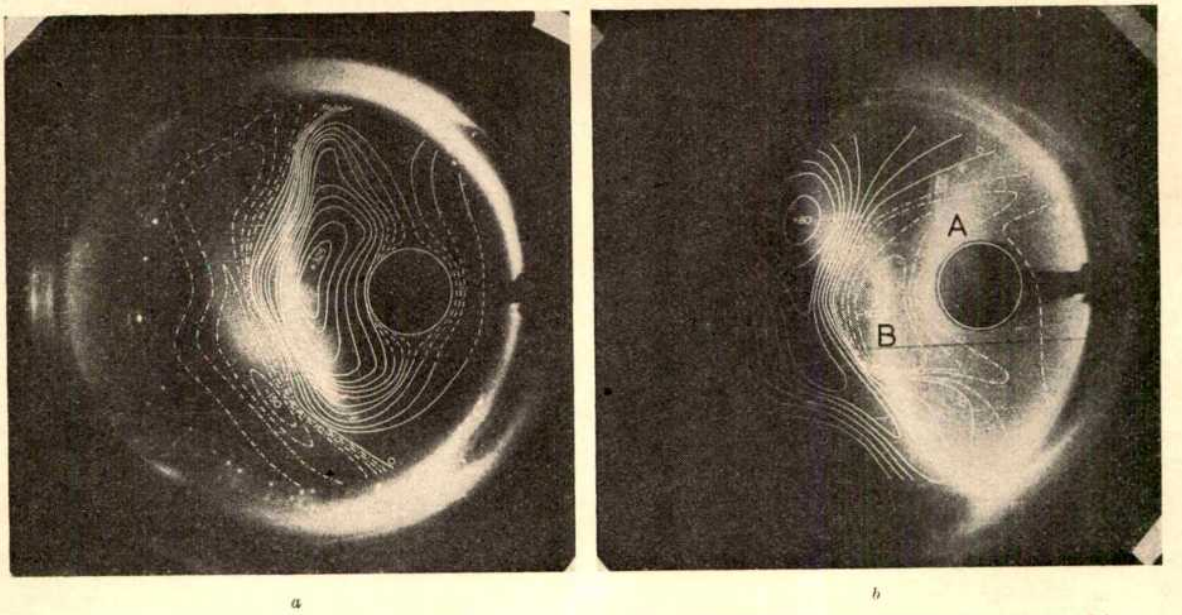


Fig. 1. Layout of the experimental system. *A*, Diffusion pump; *B*, plasma gun; *C*, dipole coil; *D*, search coil; *E*, Kerr-cell shutter; *F*, camera

The experimental arrangement was as shown in Fig. 1. A co-axial plasma gun, powered by the discharge of a 16 μF capacitor from 10·5 kV, was used to propel plasma through a vacuum chamber at a velocity of about 4×10^6 cm/sec towards the quasi-static magnetic field surrounding a dipole of moment $1{\cdot}0 \times 10^5$ gauss cm^3, with the axis of the dipole perpendicular to the plasma flow. The current through the plasma gun was prevented from oscillating by means of a fuse designed to melt after the first half-cycle of the current waveform. The dipole field was produced by the discharge of a 328 μF capacitor at 2·5 kV through a spherical coil 4·2 cm in diameter surrounded by an earthed copper screen. The firing of the plasma gun was timed to occur near the first peak of the dipole field when the field was varying only very slowly because of the long period of oscillation of the coil current.

The effects observed were reproducible, so by using several firings the sequence of events could be photographed at various pre-set delays using a Kerr-cell shutter which gave exposure times of 1 μsec. Photographs were taken looking perpendicular to the equatorial plane; and in order to determine the three-dimensional structure, others were taken with the dipole re-orientated to display the meridian plane. The temporal variations of the component of the magnetic field in the axial (north–south) direction were measured at many points in the equatorial plane by a small mobile search coil connected to an integrating circuit. The magnetic field changes were displayed on an oscilloscope and recorded photographically. The field variations were corrected for the slow change in the dipole field, which was separately observed with the search coil when the plasma gun was not operated.

a *b*

Fig. 2. Contours of equal magnetic field change superimposed on 1-μsec exposures of the plasma. *a*, 7 μsec after the plasma gun firing; *b*, 19-μsec delay

The method of presentation of the results has been chosen to show the changes in magnetic field, produced by electric currents induced in the plasma, and to compare these with the pictures of the glowing plasma obtained with the Kerr-cell camera. The values of the magnetic field perturbation at all locations at any chosen time were interpolated to build up a contour map showing lines of equal field change (rather than total field) at this time. The field-change distribution is caused by currents in the plasma, and the contours can therefore meaningfully be superimposed on to the Kerr-cell picture for the same delay time. A set of such comparison photographs were made for a succession of delay times between 4 and 27 μsec after the firing of the gun. The two photographs shown in Fig. 2, corresponding to delays of 7 and 19 μsec, illustrate important stages of the interaction and exemplify an interesting reversal of the induced field. In Fig. 2 the plasma advances from the left and the camera is situated on the dipole axis facing the south-seeking pole (corresponding to the northern terrestrial pole). The contours are at intervals of 25 gauss in Fig. 2(*a*) and 10 gauss in Fig. 2(*b*). The contours corresponding to negative field changes are shown chain-dotted and the numbers label the maximum and minimum contours. The dashed lines close to the dipole show parts of the contours the positions of which have been inferred rather than measured.

In the early stages of the interaction there was an increase in magnetic field strength near the dipole, while farther out towards the plasma source the field strength was depressed. This field distribution conforms to the usual explanation of the initial phase of a geomagnetic storm in which the incident plasma may be thought of as compressing the dipole field because of currents induced in its leading face which change the original magnetic field.

At times later than 16 μsec the general direction of the current in the equatorial plane was reversed to become westward, giving a decrease in field near the dipole but augmenting the undisturbed field at distances greater than about 8 cm from the dipole centre in the direction of the gun. The sequence of magnetic field variations near the dipole is strongly suggestive of the field changes observed at the Earth's surface during a typical magnetic storm.

The form of the induced magnetic field can be used to deduce the way in which the current is distributed in the neighbourhood of the equatorial plane. Certain types of current distribution can easily be distinguished. For example, a magnetic field strength profile resembling a step function is produced by a current sheet. On the other hand, if the current flow is more localized along a line, the step function would be modified by a rapid decrease of field with distance from the line.

Fig. 3 shows the field-change distribution along the line from the plasma gun to the dipole at the delay times shown. For times earlier than 13 μsec the shape of the curve indicates an eastward current localized near the equatorial plane. At 13 μsec the curve approximates to a step function, showing that the current was then distributed in a sheet extending some distance above and below the plane. After the current reversal which occurred at about 16 μsec, the current was again localized but appeared to be extending into a sheet as the currents decayed with the plasma. The fact that the step functions do not extend equally above and below the zero line is a consequence of the curvature of the current sheets about the dipole axis.

Referring again to Fig. 2 and ignoring the bright regions where the plasma has been intercepted by the glass walls of the vacuum chamber, we interpret the luminous areas as regions of enhanced recombination rate where the plasma density (and probably temperature) was raised. At 7 μsec, the light emission was from the region of maximum current density as indicated by the field-change contours. After 19 μsec delay the bright plasma regions were mainly nearer to the dipole than the high current density region. The bright area *A*, which seems to be in contact with the dipole coil in Fig. 2(*b*), was shown, by a meridian plane photograph taken at 19 μsec delay, to be, in fact, well removed from the equatorial plane with which we are mainly concerned here. A region of field-aligned luminosity passing through the equatorial plane is seen in region *B*, but the field-change contours show that it cannot be identified with a high current density as could be the luminosity in Fig. 2(*a*). In the early stages of the interaction, these observations are consistent with behaviour predicted by the Chapman–Ferraro model in that the plasma flow was held off, and near the equatorial plane an eastward current was induced in the advancing plasma front. Afterwards the current extended itself into a sheet at a stand-off distance of about 8 cm from the centre of the dipole. Later some of the plasma seemed to penetrate farther towards the dipole, into the 'magneto-

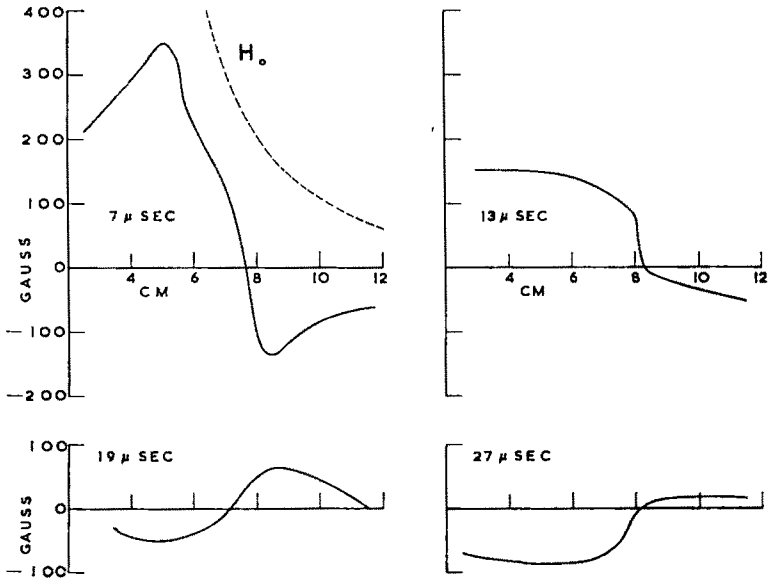

Fig. 3. Profiles of the change in magnetic field along the line from the dipole to the plasma gun at the delay times indicated. The abscissae represent distance from the dipole axis towards the gun. The undisturbed dipole field H_0 is also shown for comparison

sphere' and a westward current was set up at about the same stand-off distance. This current may be analogous to the ring current proposed in the explanation of the main phase of geomagnetic storms.

There was no strong gradient in the field-change within the region B, which thus showed that the net current there associated with the particle motion was small. This indicates, in accordance with meridian plane photographs, that B was a belt of charged particles trapped by the magnetic field. A net current carried by this belt could only be due to an approximately collisionless drift[1] produced by the field gradient, and the drift current is shown by the observed field-change distribution to be negligible compared with the west-flowing current surrounding the plasma. It appears that the dominant effect here was the injection into the initially compressed field of the 'magnetosphere' of diamagnetic plasma which lowered the magnetic flux in this region, thus necessarily maintaining a circulating current around itself and the dipole in a westward direction.

The experiment exhibits several features matching geophysical observations. A typical geomagnetic storm is probably caused by a sudden gust in the solar plasma stream passing the Earth. The initial phase of the storm is observed at the Earth's surface as an increase in the local magnetic field and is adequately explained by magnetosphere models following the ideas of Chapman and Ferraro[2,3]. The main phase of the storm, during which the terrestrial field strength stays below its undisturbed value, has proved more difficult to explain. Our experiments suggest that the decrease in field intensity could be caused by penetration of solar plasma containing little magnetic flux into the magnetosphere. The meridian plane photographs indicate that there is appreciable plasma injection along the magnetic field lines passing through the so-called neutral points over the polar regions, where even a 'closed' model of the magnetosphere is open to the plasma stream.

Bostik *et al.*[4] in a similar experiment have concluded that vortices present in the plasma flow enable plasma to break through the magnetosphere boundary. This has possibly occurred in the experiments described here and might also be important in geophysical phenomena since observations[5] have indicated that in the neighbourhood of the Earth's orbit the solar wind is highly irregular. The scale of the irregularities dominating the flow is probably between 10^2 and 10^4 km (less than one-tenth a typical magnetosphere dimension) so that the magnetosphere is set up by the average wind. If the plasma irregularities are vortices and contain closed magnetic field lines, some of these might link with the Earth's field so that penetration of the interplanetary plasma would be facilitated.

A more detailed analysis of the experimental results is proceeding and it is hoped to determine whether the characteristics of the experimental magnetosphere most resemble those predicted by the Chapman–Ferraro model and its derivatives or those expected on the basis of the theories of Alfvén[6] and Karlson[7].

OBITUARIES

Prof. S. G. Wilson, C.B.E.

THE untimely death of Prof. Samuel Geoffry Wilson came as a great shock to the veterinary world and as a still greater one to his friends and colleagues

Geoff, as he was called by those who knew him, was born in Donaghmore, County Tyrone, Northern Ireland, educated at the Royal School, Dungannon, and then went to Queen's College, Belfast, where he took a B.Sc. degree in agriculture. From there he moved to the Royal (Dick) Veterinary College, Edinburgh, and obtained the degree of M.R.C.V.S.

In 1936 he was awarded a colonial scholarship and went to Nyasaland (now the Malawi Republic) where, among other duties, he studied ticks and tick-borne diseases; for these researches he was awarded a Ph.D. degree in 1946. In fact, he was a recognized authority on ticks in Africa.

At the same time he had a very keen interest in tsetse and trypanosomiasis problems and in 1947 transferred to Uganda as chief veterinary research officer at Entebbe. In 1949 he took up the post of chief field zoologist in the Tsetse and Trypanosomiasis Control Division of the Kenya Veterinary Department. In 1952 he became director of veterinary services in Northern Nigeria. He retired from Government service in 1962.

Later in 1962 he was appointed professor and director of the Institute of Tropical and Protozoal Disease in the Veterinary Faculty of the State University of Utrecht. There he remained until he died in September 1965. He was 55 years old.

Geoff Wilson was full of drive, enthusiasm and energy. He was also bold and quick to see the practical application of new developments—the ideal man to introduce modern and progressive methods.

In Uganda he studied trypanosome infections in cattle, sheep and goats, carried out some early trials with the new trypanocidal drug 'Antrycide' and investigated drug

resistance acquired by trypanosomes resulting from underdosing with 'Antrycide'.

In Kenya he started an insecticidal tsetse eradication scheme in the Nyando river basin near Lake Victoria, in collaboration with the Tropical Pesticide Research Institute. This project was to have far-reaching effects on the sleeping sickness problem in that country, for it was the first successful large-scale residual insecticidal project undertaken against *Glossina* in East Africa.

When he went to Nigeria he immediately recognized the urgent necessity of 'Nigerianizing' his department and began at once to do so. Again, with his characteristic foresight and drive, he lost no time in forming a Veterinary Tsetse and Trypanosomiasis Unit, staffing it with the best men he could find, and sent an officer to Kenya to examine the methods in use there. The next step was the Komadugu Ghana scheme, the biggest, boldest, most successful and cheapest residual insecticidal spraying operation ever undertaken against the tsetse flies *Glossina morsitans submorsitans* Newstead and *G. tachinoides* Westwood in the Sudan zone of Northern Nigeria. This work was followed up by even larger schemes and to-day the Northern Nigerian Veterinary Tsetse and Trypanosomiasis Unit ranks among the best and most up-to-date organizations of its kind in Africa. In recognition of his outstanding services he was awarded the C.B.E. by Her Majesty the Queen.

Geoff Wilson was a man of many parts, and two years after his appointment as professor at Utrecht he gave an inaugural address entitled "The Problems of Trypanosomiasis Control in Cattle in Africa", ending up by speaking for 10 minutes in the Dutch language. But he had lost his heart to Northern Nigeria, and through his influence the 'Zaria Project' involving a part of the Veterinary Faculty of the new Ahmadu Bello University, supported by Dutch aid, came into being.

Apart from his numerous scientific interests and achievements, Geoff was an accomplished sportsman. As a boy he played rugby for the Ulster Schools side and later won his boxing blue at Edinburgh—he was Scottish Universities Welterweight Champion for 1933–34.

Besides his wife, Maureen, he leaves behind two sons and a daughter. His eldest son is a veterinarian following in his father's footsteps, for he has recently taken up a post with the East African Trypanosomiasis Research Organization at Tororo in Uganda.

Geoff was Irish to the finger-tips—kind, generous and considerate to his friends and a thorn in the side of his enemies—he will be sorely missed. P. E. Glover

Prof. S. K. Allison

Samuel King Allison, director of the Enrico Fermi Institute for Nuclear Studies and the Frank P. Hixon distinguished service professor in the Department of Physics at the University of Chicago, died on September 15, 1965, in England.

Prof. Allison was serving as the United States delegate to the Plasma Physics and Controlled Nuclear Fusion Research Conference under the sponsorship of the International Atomic Energy Agency in Culham, near Oxford. He suffered an aortic aneurism on September 6, and underwent surgery at the Radcliffe Infirmary, Oxford. Death was attributed to a pulmonary embolism.

Allison was one of the best known and best loved of American scientists. Born in Chicago in 1900, the son of a Chicago public school principal, he was a product of the community of which the University of Chicago is a part. He was educated in the Chicago public schools, received his B.S. degree from the University of Chicago in 1921 and his Ph.D. degree two years later. Following a period as National Research Fellow at Harvard University (1923–25) and as Fellow at the Carnegie Institution (1925–26), he joined the faculty at the University of California, Berkeley, but returned to the University of Chicago in 1930 after having achieved the rank of associate professor.

Allison's early researches at Berkeley and Chicago were in X-rays. His major work involved the design and construction of a high-resolution double crystal spectrometer, its application to the measurement of the widths and intensities of X-ray lines, and to the experimental confirmation of the C. G. Darwin–P. P. Ewald dynamical theory of X-ray diffraction. The depth of his understanding of the field of X-rays is evident from the book he wrote jointly with A. H. Compton, *X-rays in Theory and Experiment*, a classic text in the field.

His interest turned to nuclear physics during the middle 1930's. He concentrated on the reactions among the light elements that could be examined with accelerators of relatively low energy. The Cockcroft–Walton accelerator which he built himself and operated with his students developed a maximum of 400 kV. He dubbed it *Kevatron* to emphasize its modest capabilities at a time when his associates were constructing machines in the million- and then the billion-volt range. Yet the *Kevatron* kept turning out a continuous stream of interesting research and a continuing succession of able graduate students. Much of the research which he carried out together with his students concerned precise measurements of the energy released in proton-induced reactions. In later years this interest shifted to the reactions induced by heavier ions. He was particularly successful in developing sources of lithium ions. To pursue these reactions more extensively, he needed higher energy machines. The University made available to him its 2-MeV Van de Graaff, acquired originally for biological studies. In the end he obtained a 4-MeV machine with a grant from the National Science Foundation.

A subsidiary interest which grew into a major activity was the investigation of the energy loss of charged particles moving through gases. This developed into an extensive investigation of the mechanism of capture and loss of electrons by the ions, a subject that turned out to give important insights into plasma physics and the quest for ways to harness thermonuclear fusion. For these studies the *Kevatron* continued to play a central part until the end.

Allison's emergence into public life had its origins in the secret wartime enterprise that developed the atomic bomb. He began, in January 1941, to investigate the suitability of beryllium as a moderator of slow neutrons for the chain reaction. The work was done with a grant of 9,000 dollars, obtained from the U.S. Office of Scientific Research and Development. Writing about this later, he commented, "I remember being aghast at the ease with which this seemingly colossal sum was placed at my disposal". This work has remained of fundamental interest and serves now as the basis for certain major lines of nuclear reactor development. Although beryllium, because of its scarcity, did not occupy a prominent place in the initial development of the chain reaction, Allison's early effort served to focus that development at the University of Chicago. His group at Chicago was joined by Fermi's Columbia group and Wigner's Princeton group when, in February 1942, the "Metallurgical Laboratory" was organized under the leadership of A. H. Compton to develop a method for producing plutonium as a possible material for the atomic bomb. It was this Laboratory, at the University of Chicago, that successfully achieved the first nuclear chain reaction in December 1942.

Allison liked to recall his role on the occasion of the first chain reaction experiment. He was the leader of the "suicide squad". It was his brawn, not his brain, he insisted, that qualified him to be entrusted with the ultimate, last-ditch measure. It was his idea to prepare a huge jug of cadmium solution, and he stood ready to pour it over the chain-reacting pile in the event of all other control mechanisms failing to operate.

The work of the Metallurgical Laboratory led directly to the large-scale production of plutonium, out of which

the first nuclear bomb was constructed. Allison served in this project from its beginning until 1944. He served as director of the Laboratory during the final year of this period. He jested that his main job was to sign the huge stacks of blueprints and documents having to do with the construction of the great nuclear reactors at Hanford.

In November 1944, he went to the Los Alamos Laboratory to work more directly on the development of the atomic bomb. He served as chairman of the Technical and Scheduling Committee which scheduled the final stages of the test of the first atomic bomb on July 16, 1945. He made history when his voice sounded across the New Mexico desert, counting off seconds to zero on that memorable dawn that witnessed the first nuclear explosion.

September 1, 1945, was the day on which the University of Chicago announced the formation of its new research institutes with Allison as the newly appointed director of the Institute for Nuclear Studies. Such luminaries as Enrico Fermi and Harold Urey were already enlisted as members. It was on this occasion that Allison made what came to be known as "Sam's butterfly speech". He warned that if the exchange of scientific information was prohibited by military regulation, scientists in America would leave the field of atomic energy and devote themselves to such subjects as the colours of butterfly wings. The speech became the opening salvo in the campaign the scientists fought to prevent military control of the peacetime development of atomic energy.

He served as the first director of the Institute of Nuclear Studies (later renamed for Enrico Fermi) until his death, except for one five-year interlude. The Institute was devoted to the idea that physicists, chemists, and astrophysicists had complementary interests and could work together under one roof with mutual benefit. Under Allison's stewardship the Institute flourished. The seminars were brightened by such men as Fermi, Teller, Urey, J. Meyer, Wentzel, Chandrasekhar, Gell-Mann, and Dalitz. Many new ideas were developed, among them two that have already won Nobel prizes: radio carbon dating (W. F. Libby) and the nuclear shell model (M. G. Mayer).

Allison was awarded the Medal of Merit for his work on the atomic bomb: he was a founding member of the Board of Sponsors of the *Bulletin of the Atomic Scientists*. He was elected a member of the National Academy of Sciences in 1946 and served as chairman of its Physical Section from 1960 until 1963. He served as guest lecturer and adviser in nuclear physics matters on several occasions in Spain, in Argentina, and in the United Arab Republic.

Allison was a large man and his tall stature and silvery-white hair gave him a striking presence in any gathering among men. It was difficult to disturb his sense of equilibrium and he had an air of imperturbable calm that made doubly effective the sound common sense he could interpose at the propitious moment in colourful but clear and quotable language. He never failed to find a humorous side to every situation, however tense.

He enjoyed the life of teaching and research. He never lost an opportunity to work in the laboratory with his own hands. He had a natural talent and the requisite patience for making his apparatus work and he took a particular pride in displaying these skills to his students.

He was a man who asked little but gave much. His friends, colleagues and former students mourn their loss.

H. L. ANDERSON

Dr. H. R. Lang

DR. HERBERT RAPHAEL LANG, who died suddenly on November 18 at the age of sixty-one, had been secretary of the Institute of Physics, and afterwards of the amalgamated body of the Institute of Physics and the Physical Society, since 1932. His connexion with the Institute went even further back than this and he was present as a schoolboy at the inaugural meeting in 1921. Lang read physics at the Imperial College of Science and Technology, and after his first degree continued as research student and demonstrator, gaining his Ph.D. for work on the investigation of the effect of temperature on the specific heats of liquids. His work on the thermal properties of liquids continued after his appointment to a research Fellowship by the Institute of Petroleum. He could have made an outstanding career in research or in industry but, fortunately for the physics profession, he was persuaded to become secretary of the Institute. It is difficult to imagine anyone better suited for such a post. Apart from his deep interest in physics he had a rare combination of wisdom, realism, determination and loyalty, as well as an enormous capacity for hard work, and above all a kindly and unselfish nature. No task associated with physics was too great or too small for him, whether it was organizing an international conference, forming a new subject group, giving professional advice to a junior colleague or operating the benevolent fund.

Lang was, by nature, shy and retiring. Although most members of the Institute and Society realized that he played a very large part in its affairs, it was only those who were privileged to work closely with him who fully appreciated the extent of his efforts and devotion. His work was conducted largely behind the scenes and he sought no personal credit. New developments and policies which were largely inspired by him were usually presented to the members through the honorary officers. At the same time, he was always ready to give credit to his own staff.

When Lang took office in 1932 the physics profession, as such, barely existed. To-day there are more than eleven thousand members, drawn from academic establishments, industry and government service. Under Lang's guidance, this vast number of pure and applied physicists, distributed throughout the United Kingdom and abroad, have developed, through the branches and specialist groups, common interests and activities, and a sense of belonging to the profession. From his early days in the Institute of Physics, Lang maintained close contact with the Physical Society, and it was due in no small measure to his untiring efforts during many years that amalgamation of the two bodies was effected in 1960.

Physics owes much to Lang and he will be greatly missed. He leaves a widow and three sons.

M. R. GAVIN

W. B. Alexander

W. B. ALEXANDER, formerly director of the Edward Grey Institute of Field Ornithology, University of Oxford, died on December 18, 1965, at the age of eighty. He was educated at Bootham School, York, Tonbridge School, and King's College, Cambridge. The Cambridge degree ceremony then involved a procession, headed by the first-class honours men (in alphabetical order) from the college providing the Vice-Chancellor, and in 1909 it was led by W. B. Alexander and the man he referred to as 'young Brooke'. After brief appointments in the Cambridge Museum of Zoology and then as assistant naturalist to the Board of Fisheries (North Sea), he accepted, in 1912, the post of assistant in the Western Australian Museum, Perth, and was Keeper of the Biological Department there from 1914 to 1919 (apart from two years in Melbourne on war work as a science abstracter). In this period he revitalized the Perth museum. After a brief return to England, he was biologist to the Prickly Pear Board from 1920 until 1925, and thus a prominent member of the team which effected one of the most successful examples of biological control of a pest ever recorded, Alexander being the man who first brought live *Cactoblastis* from South America to Australia. While in Australia he also played a prominent part in the Royal

Society of Western Australia and the Royal Australian Ornithologists' Union, and he is warmly remembered by Australian ornithologists.

On his voyages to England in 1920 and 1926, he was struck by the difficulty of identifying sea-birds, and this resulted in his best-known work, *The Birds of the Ocean*, published in 1928, which may fairly claim to be the first ornithological field guide. After 3 years without a regular post (he was a bachelor with modest private means), he was in 1929 appointed superintendent of the Tees survey of the Marine Biological Association. He left this post in October 1930 to become director of the Oxford Bird Census, founded by E. M. Nicholson, the late B. W. Tucker and the Oxford Ornithological Society, which, after the creation of the British Trust for Ornithology in 1933–34, became the Institute of Field Ornithology, and in 1938 the Edward Grey Institute. In his period as director, he played a valuable part in encouraging undergraduate ornithologists, and it was after taking undergraduate parties to trap migrants on Holy Island in 1931 and 1932, and a visit with senior ornithologists to Heligoland in 1933, that Alexander stimulated the founding of the first British Bird Observatories, on Skokholm and the Isle of May. His other main service was to build up the library of the Edward Grey Institute, much of it from his own pocket, as funds were very low. When he retired as director in 1945, he remained as librarian for a further ten years, and the library was named after him. His remarkable memory, usually precise to the part of a page, helped all in search of information. By now, the Alexander Library is probably the most complete ornithological library in the world, and the residue of Alexander's estate has been bequeathed to it.

D. Lack

NEWS and VIEWS

The Academy of Sciences of the U.S.S.R.: Foreign Members

Thirty-five scientists were elected Foreign Members of the Academy of Sciences of the U.S.S.R. at the recent meeting in Moscow. Included among these were four British scientists: Lord Florey, past-president of the Royal Society, and Provost of The Queen's College, University of Oxford; Prof. P. M. S. Blackett, president of the Royal Society and emeritus professor of physics, University of London, and part-time scientific adviser to the Ministry of Technology; Sir Robert Robinson, past-president of the Royal Society and emeritus professor of chemistry, University of Oxford; and Sir Geoffrey Taylor, formerly Yarrow research professor of the Royal Society. The total number of Foreign Members of the Academy of Sciences of the U.S.S.R. is now seventy-three.

Honorary Fellowship of the Institute of Mathematics and its Applications: Sir Geoffrey Taylor, F.R.S.

The Institute of Mathematics and its Applications has elected Sir Geoffrey Taylor as its first Honorary Fellow. Sir Geoffrey, who will celebrate his eightieth birthday on March 7, 1966, has made distinguished mathematical and experimental contributions to the mechanics of fluids and solids and their technological and geophysical applications. He was elected to Fellowship of the Royal Society in 1919 and received the Copley Medal in 1944. From 1923 until 1952 he was a Yarrow research professor of the Royal Society. Sir Geoffrey Taylor has been honoured by universities, academies and societies throughout the world. A formal presentation of the certificate of honorary fellowship will be made at the Imperial College of Science and Technology, London, in the Department of Physics on February 23, immediately preceding a lecture to the Institute by Dr. J. W. S. Cassels on "What are p-Adic Numbers?"

The Scottish Horticultural Research Institute, Mylnefield, Invergowrie: Dr. T. Swarbrick, C.B.E.

Dr. T. Swarbrick retired from the post of director of the Scottish Horticultural Research Institute, Mylnefield, Invergowrie, on January 31, 1965. He was appointed as the first director of the Institute on its establishment in 1951 and his retirement after 14 years thus marked the end of the first phase in the development of this important centre of horticultural research in Scotland. Dr. Swarbrick received his scientific training at the University of Leeds, where he graduated in agriculture and botany (1923), B.Sc. Hons. in botany (1924) and Ph.D. in plant physiology (1927), after holding a Ministry of Agriculture scholarship at Leeds, Long Ashton and Wisconsin (U.S.A.). On completing his training, he served on the staff of the Long Ashton Research Station first as physiologist and later as pomologist until 1945, when he joined the scientific staff of the Royal Dutch Shell Group, with headquarters in The Hague and Amsterdam. This was followed in 1951 by his appointment at Mylnefield, where he had the task of establishing and developing this new research centre to serve the special needs of the Scottish horticultural industry. In developing the research programme there, Dr. Swarbrick used as a basis the research units of the Department of Agriculture for Scotland for the investigation of diseases of raspberries and strawberries at Dundee and Auchincruive, and these subjects are still prominent in the present programme. Other important subjects of investigation include the breeding of raspberries, strawberries and vegetables, and the occurrence of natural growth substances in the strawberry in relation to environmental factors and developmental effects. Mylnefield, under Dr. Swarbrick's able guidance, has become a national research centre of repute and is a fitting memorial to his scientific ability and vision, his drive and enthusiasm, and his high personal qualities. His distinguished work there was officially recognized by the award of a C.B.E. in 1964; he has received the 1965 Scottish Horticultural Medal.

Organization for Economic Co-operation and Development

The Organization for Economic Co-operation and Development (O.E.C.D.), successor to the Organization for European Economic Co-operation (O.E.E.C.), was established in 1961; it comprises all the industrialized countries of North America and Western Europe, and also Japan. Three major aims guide its policy: first, promotion of the highest sustainable economic growth and employment and a rising standard of living in the member countries; secondly, support for sound economic expansion of member and non-member nations in the process of development; and thirdly, furtherance of the expansion of world trade on a multilateral, non-discriminatory basis. This Organization functions primarily as a forum for policy-making representatives of member Governments, and a brief account of its work has previously been noted in these columns (*Nature*, 205, 1098; 1965). To take one example, agriculture, ". . . Because of the difficulties encountered in adapting national agricultural policies to the requirements of fuller co-operation, agriculture has often been considered an obstacle to co-operation. So far

as agriculture is concerned, it is the function of O.E.C.D. to promote the transformation of agricultural policies to meet changes in the position of agriculture within and between countries".

This and much other information on the work of the Organization in this field is contained in an article, "Agriculture in an Industrial Economy", contributed by the Directorate for Agriculture, O.E.C.D., Paris (*Span*, 8, No. 3; 1965. Shell International Chemical Co., Ltd., Shell Centre, London, S.E.1). *Span* is an attractive and extremely well-presented magazine, published three times a year, and this particular issue contains a number of articles by different authors, the subjects ranging from pesticides, agricultural extension in the United States, a modern dairy farm in Thailand, Chinese market gardening in Malaya, urbanization and filariasis, tsetse eradication in Uganda, to the work of the Indian Agricultural Research Institute, which in 1965 celebrated its Diamond Jubilee.

Other interests and activities of the O.E.C.D. are chronicled regularly in the bi-monthly magazine, *The O.E.C.D. Observer* (in French and English). In a recent issue (No. 18; October 1965. O.E.C.D. Information Service, Château de la Muette, Paris), subjects dealt with are, *inter alia*: the high-level meeting of the O.E.C.D. development assistance committee; international payments; housing construction policies and techniques in Switzerland; a development plan for the Mediterranean coast of France; agriculture as a positive force in the growth process; and O.E.C.D. experience in efficient use of resources for school building. The Organization is responsible for many other publications covering a wide range of topics, as a list of recent titles in this issue makes clear. The new titles are: "Fish Handling and Preservation"; "Women Workers, Working Hours and Services"; "Wages and Labour Mobility"; "Teaching Physics Today"; and "International Standardization of Fruit and Vegetables", all being evidence of the practical manner in which the fundamental aims of the O.E.C.D. are being furthered and realized.

Scientific Research in France

Le Progrès Scientifique (No. 89; October 1965) contains a broad outline of the fifth Plan for Scientific and Technical Research in France (1966–70), on which 3,600 million francs are to be expended, with 600 million francs for development. This includes all expenditure on fundamental or applied research not under the military or space programmes or on the Atomic Energy Commission. 2,000 million francs are provided for space research, of which 450 million francs are for the European programme. Of the 3,600 million francs, 1,254 million francs are for physics, 590 million francs for biology and medicine, 400 million francs for chemistry, 390 million francs for agricultural research, 315 million francs for mathematics, 284 million francs for the sciences of the Earth, water and atmosphere, 150 million francs for oceanography, 120 million francs for the human sciences, and 162 million francs for construction, public works, urban studies. Some 43,350 research workers and technicians were available in 1963, of whom 11,180 were in the natural and exact sciences, 19,160 in engineering, 8,410 in medicine and pharmacy, and 4,600 in the human sciences. Of the total, 16,530 were in higher education, 17,350 in professional and non-profit institutions, 4,310 in the Centre for Research in Nuclear Science, 2,540 in the Prime Minister's or Defence Ministry, and 2,620 in other technical ministries. The total is expected to increase by 35,000 during the period.

The Netherlands Delta Plan

SINCE time immemorial, the delta area lying south-west of Rotterdam in The Netherlands has been a 'half-open door' through which the North Sea, in its stormier moods, has poured, inundating towns and villages, washing away precious topsoil and choking the land with a surfeit of salt. The tragic floods of 1953, when more than 1,800 people lost their lives, 72,000 people had to flee from their homes south of Rotterdam, 800 miles of dykes were wrecked, 500,000 acres of land overrun, some 200,000 animals destroyed on Dutch farms, to say nothing of 10,000 houses, schools and churches destroyed, all taught a grim lesson. Shortly after this great disaster, what was known as the Delta Commission was formed in The Hague, its task to find a practical means of beating these terrible incursions of the North Sea for ever. One project was to raise the level of existing sea dykes; an alternative was the imaginative scheme of damming up the sea arms of the delta altogether. The Dutch have a fanatical and historical enthusiasm for land reclamation, and it was this second scheme that was recommended by the Commission, adopted by the Minister of Transport and Waterways, eventually approved by the Dutch Parliament, and consolidated under the Delta Act. The Delta Plan, as it is known, is undoubtedly one of the outstanding civil engineering ventures of this or, for that matter, any other age; it is estimated that it will take 25 years to complete; it will shorten the country's coastline by more than 400 miles, at an estimated cost of some £250 million.

In a strikingly illustrated article entitled "Against the Sea" (*Esso Magazine*, 4, 14; Autumn 1965. Esso Petroleum Co., Ltd., London, S.W.1), some details are given of this ambitious undertaking, including a map of the Delta Plan, giving the dates of starting and completing the major projects. The seven main constructions are Haringvliet, between Voorne and Goeree (1957–69); Brouwershavense Gat, between Goeree and Schouwen (1962–72); Oosterschelde, between Schouwen and Noord Beveland (1965–78); Veerse Gat, between Noord Beveland and Walcheren (1956–61); Zandkreek, between Noord Beveland and Zuid Beveland (1958–60); Grevelingen, between Overflakkee and Duiveland (1958–64); and Volkerak, between Hoeksche Waard and Overflakkee (1957–67); the years in parentheses are starting and finishing dates. The dams in the Haringvliet, Brouwershavense Gat and Oosterschelde are all major sea walls, the last-mentioned being the longest and heaviest dam in the whole scheme. The Haringvliet is the estuary through which more than half the waters of the Rhine and the Meuse empty into the North Sea. The Dutch want to hold and store as much of this water as possible in large fresh-water lakes, which will be constructed when the Delta Plan is complete, but at the same time they want to control the efflux of surplus water into the North Sea by means of seventeen sluices, each 185 ft. wide.

The Delta Plan will eventually secure the safety of the existing land; it will combat salination of rivers and adjoining channels, thus increasing agricultural production. The islands of the Delta will no longer be isolated; new roads will run on top of the new dykes, providing fast links with Belgium, Rotterdam and towns beyond in The Netherlands. A new natural playground will be created in this region, a country of wooded lakes and sandy beaches, an added attraction to tourists. The one disadvantage of this Delta Plan is that with the exclusion of the sea, once it is completed, the fisheries, oyster and mussel beds, so long characteristic of Zeeland, will disappear; but, it is argued, this is perhaps a small price to pay for beating the destructive power of the North Sea for ever in this enterprising country.

Research in Chemical Information

ACCORDING to *Scientific Information Notes* (7, No. 5; October–November 1965), the National Bureau of Standards, in connexion with the Chemical Information Programme of the National Science Foundation, is to investigate fragmentation codes for preparing indexes of chemical structures, and searching techniques for specific and generic chemical structures represented as connexion

tables. The Bureau will also investigate file organization, to develop means for storing specific categories of data, and will continue previous work on extending and mechanizing various linear notations. The research group will work in close co-ordination with the research and development group of the Chemical Abstracts Service, which is also supported by a contract from the Chemical Information Programme.

Jena Review

The *Jena Review* (*Jenaer Rundschau*, as it is more widely known) was first published in 1956 and has recently celebrated its tenth anniversary in a number to which no less than seven Nobel Prizewinners contribute (*Jena Review*. VEB Carl Zeiss Jena. VEB Verlag Technik, Oranienburger Str. 13/14, Berlin C 2. No. 5; 1965). This enterprising house journal is now available in English, French, Russian and Spanish, besides the original German. Following the editorial by Dr. H. Schrade entitled "Ten Years of Jena Review", articles by the seven eminent scientists are: "The 'False Trans-uranic' Elements", by Dr. O. Hahn, Göttingen; "Stable Isotopes", by Dr. G. Hertz, Berlin; "Symmetry and Invariance", by Dr. E. P. Wigner, Princeton, New Jersey; "The Part played by Pure Science and the Progress in High-Energy Physics", by Dr. C. P. Powell, Bristol; "Critical Opalescence", by Dr. P. J. W. Debye, Ithaca, New York; "Seeing and the Nature of Light", by Sir C. V. Raman, Bangalore; and "Celebration of the Award of the 1964 Nobel Prizes", by Dr. A. Tiselius, Uppsala. Other contributions are "Structure of Liquids and the Formation of Glass", by Dr. W. A. Weyl, Pennsylvania State University; "The Importance of Walter Nernst", by Dr. K. Schwabe, Dresden; and an obituary notice of the late Dr. Hans Boegehold, for 57 years with Zeiss, by Dr. H. Schrade. *Jena Review* appears bi-monthly; it is always well printed and produced, and the illustrations, both in black-and-white and in colour, are of consistently high quality. Although originally founded to be ". . . a bridge and a linking of all the friends of the scientific and technical work of VEB Carl Zeiss Jena to all users of Zeiss equipment in every country throughout the world", in which aspiration it has certainly succeeded, this magazine is never a collection of explanatory advertisements; it is a welcome vehicle of up-to-date technical information, especially in the field of optical instruments and physics.

The Museums Journal

The December issue of *The Museums Journal* follows the pattern of previous issues and is mainly devoted to a single theme (65, No. 3; 1965). The articles help to define some areas of work with art collections. One concerns a regional art collection and the problems it poses of balance and specialization, while another depicts the work of an art dealer from his side of the desk. The applied arts are no less complex than the fine arts, and a paper on furniture introduces a field of study which has recently generated a new society devoted to its history. The new processes used for the reproduction of relatively large numbers of lithographs are described. All these articles will help reflection on the role of a curator in an art gallery. The concluding article describes museum and art gallery buildings erected between 1845 and 1914.

Sarawak Museum

The Sarawak Museum Journal, edited by the curator, Mr. Tom Harrisson, includes an interesting set of papers, among which is a comprehensive study of the Sarawak Malays by the editor (11, Nos. 23–24. (New series.) Pp. xii+341–666. July–December 1964. 5 dollars; 12*s.* 6*d.*). This paper will form the opening chapters of a book on the subject to be published in 1966. Other articles include notes on the descent of some Saribas Malays, Sarawak Malay pottery, some Baram coffin burials, Papuan stone adzes, an introductory vocabulary of Suluk, Sarawak relations with Britain 1858–70 and Borneo maps of sixteenth and seventeenth centuries.

Transvaal Museum

The Annals of the Transvaal Museum comprises an account by Hans John (Germany) of the species of the coleopterous family Discolomidae collected between 1960 and 1962 during field research on the humicolous fauna (25, No. 1: *Sudafrikanische Discolomidae* (*Coleoptera*). Von Hans John. Pp. 19. Pretoria: Transvaal Museum, 1965). Included also is a paper by Jean Thérond (France), detailing the species collected in Southern Africa during recent Transvaal Museum expeditions (25. No. 2. Pp. 14).

The National Central Library

The forty-ninth annual report of the Executive Committee of the National Central Library covers the year ended March 31, 1965, in which the number of applications increased to 119,468 (107,742 in 1963–64), 77 per cent being satisfied, compared with 78·75 per cent in 1963–64 (Pp. 24. London: The National Central Library, 1965). Of the applications, 92,844 were for books and 26,844 for periodicals: of those satisfied, 38,318 came from public libraries, 20,895 from university libraries, 12,007 from special outlier libraries, 2,608 from Government libraries and 4,727 from overseas libraries. British libraries made 4,150 loans to overseas libraries (3,739 in 1963–64) and borrowed 3,863 items from overseas (3,488 in 1963–64); 577 photocopies were supplied to foreign libraries and 1,417 obtained. Of the fifty-eight lending countries, West Germany was the chief, followed by the Soviet Union, the United States, East Germany and France. West Germany was also the principal of 36 borrowers, followed by Hungary, the Soviet Union, Denmark, Czechoslovakia and East Germany. The United States was the chief source of photocopies and Bulgaria the chief recipient. The 384 outlier libraries satisfied 21,278 applications, and other special libraries another 8,313. In addition to 24,468 loans made at the direct request of the National Central Library, university libraries lent 17,445 items as members of regions. A further 15,000 books were catalogued and housed at the Woolwich building, bringing the total to 82,000, and the *Survey of Applications, January 1–June 30, 1964*, is now being examined by the Executive Committee. The first stage of the unification of the catalogues was completed and the British Union Catalogue of Periodicals was continued from 1960 on a new basis. The Treasury grant for the year was £105,000 (£95,000 in 1963–64). The National Committee on Regional Library Co-operation and the Implementation Committee both met twice during the year.

Indexes and Indexing

Of how many authors of scientific books can it be said with Goldsmith that "He writes indexes to perfection"? Time and again reviewers are critical of the adequacy (or lack of adequacy) of the index to a volume crammed full of academic or technical detail, of which the contents page or chapter headings suffice for direction, with perhaps only a skeleton index to the main subjects to assist the reader. Codes of practice exist as guidance to authors in preparing scientific papers for publication, on the style in which they should be presented, on the proper arrangement of references and quotations, even to instructions on desirable forms of illustration; but there are still no precepts generally accepted, let along followed, on the subject of indexing for its own and especially for the reader's sake; this, despite a British Standard on *Alphabetical Arrangement*, which is a set of rules designed to secure uniformity in the alphabetical arrangement of items in indexes, catalogues and lists of all kinds (1749;

1951. Pp. 12. British Standards Institution, London). After all, many scientific and technological books are, in fact, a series of related papers, treating logically of various phases of a specific subject; as such, they merit a proper and comprehensive index, not only for the student of the subject, but even more for others, perhaps in different disciplines, who have to refer quickly to relevant author or subject details. At the other extreme, there is the type of index which is self-defeating because it emphasizes the wrong word, for example, the adjective, not the noun.

A case in point is emphasized by the writer of a notice of a recent British official technical publication, *Research on Road Traffic* (Pp. 517. London: H.M.S.O. 42*s*.) in the *Road Research Unit Newsletter No.* 9 (October 1965. National Roads Board, New Zealand: Wellington, P.O. Box 8024). After paying tribute to this volume, he says: "It is easy to criticize the layout of indexes; yet many criticisms deserve attention. The main charge is against 'hybridization' which supplants the essentials". He comments on ". . . the format technicalities . . . obsessed with system rather than with simple usage" and goes on to say: "Nothing produces such exasperation in a reader as a hunt for relevant figures, diagrams, tables, plates . . . which are each given separate numerical sequences; and therefore 'it's every man for himself' ". Instances are quoted: 'Safety Kerbs' are not shown under 'K' or 'S'; they appear under 'C' and 'R'; 'Barriers' do not appear under 'B', but under 'R' they get two mentions; the list is extended. This writer also makes the foregoing point that indexes so often fail because the author insists on giving preference to an adjective rather than to the basic noun. In many text-books the ideal in indexing is achieved where author and subject indexes are separated; where the subject index really does list the essential nouns in each chapter, whether preceded by capital letter or in lower case, followed by as many qualifying adjectives as may be appropriate. But what is here called 'typographic pedantry' is surely to be avoided at all costs. An example of a clear, concise, rapidly informative subject index is the *Index to N.B.R.I. Information Sheets* recently received (National Building Research Institute, South African Council for Scientific and Industrial Research. CSIR Technical Note *X/BOU* 100; Building Series Dis. 100. Pp. 10. Pretoria, May 1965). But a model for authors is undoubtedly the *Subject Index to List of British Standards*, included in each annual volume of the *British Standards Yearbook*; for the art of indexing and particularly of cross-referencing, this takes a lot of beating.

Check-list of British Lichens

A NEW check-list of British lichens was published by the British Lichen Society in the 1965 number of *The Lichenologist*. It was prepared by P. W. James, of the British Museum (Natural History). The list is notable for aligning the names of the 1,347 British species with those used elsewhere in the world, while ensuring that the nomenclature conforms to the *International Code of Botanical Nomenclature*. Interleaved copies of the check-list are obtainable from the treasurer of the British Lichen Society, Dr. T. D. V. Swinscow, 103 London Road, Knebworth, Hertfordshire, price 7*s*. 6*d*., post free.

Lady Tata Memorial Trust International Grants, Scholarships and Fellowships for Research on Leukaemia and Allied Conditions

THE Trustees of the Lady Tata Memorial Trust invite applications for fellowships, scholarships and grants for research on leukaemia, in the academic year beginning October 1, 1966. In view of the affinity between leukaemia and other forms of neoplastic disease, candidates with programmes of research on any aspect of malignant disease which may throw light on problems of leukaemia will be eligible for consideration. The Trustees specially wish to encourage investigations of the leukaemogenic viruses in mammals, the epidemiology and natural history of leukaemia, and the immunogenic aspects. The awards offered by the Trust are open to suitably qualified investigators of any nationality, working either in their own institutions or in other centres abroad. Further information and forms of application can be obtained from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London, S.W.3. Applications must be submitted before March 31, 1966.

Fulbright Travel Grants

UNDER the provisions of the Fulbright programme, travel grants are available to citizens of the United Kingdom and dependent territories to go to the United States of America for academic or educational purposes, provided that they have adequate financial support in dollars for the proposed period of the visit to the United States. Those applicants who are graduate students must show proof of the admission to an institution of higher learning in the United States for a minimum period of nine months, whereas those who are professors, lecturers and senior research scholars must hold an appointment to undertake lecturing or advanced research at an approved American institution of higher learning. All grants cover the cost of direct round-trip travel between a candidate's home and the American university or institution. For graduate students the departure dates are between June 1, 1966, and July 31, 1966, for which applications must be received before April 1, 1966; and between August 1, 1966, and April 1, 1967, for which applications must be received before May 15, 1966. For professors, lecturers and senior research scholars the departure dates are between June 1, 1966, and July 31, 1966, for which applications must be received before March 16, 1966; and between August 1, 1966, and April 1, 1967, for which applications must be received by June 1, 1966. Application forms and further information can be obtained from the United States–United Kingdom Educational Commission, 71 South Audley Street, London, W.1.

Endeavour Prizes

PRIZES totalling more than £200 are offered by Imperial Chemical Industries, Ltd., publishers of the international scientific review, *Endeavour*, for essays submitted on scientific subjects. In addition to the cash prizes, the prizewinners will receive invitations to attend the whole of the British Association meeting at Nottingham during August 31–September 7. Accommodation will be provided in Nottingham and travelling expenses within the United Kingdom will be paid. As the primary purpose of these awards is to stimulate younger scientists to take an interest in the work of the British Association and to raise the literary standard of scientific writing, the competition is restricted to those whose twenty-fifth birthday falls on or after September 1, 1966. Five prizes will be awarded, namely: a first prize of 100 guineas; a second prize of 50 guineas; a third prize of 25 guineas; and two special prizes of 10 guineas each for competitors who have not passed their eighteenth birthday on September 1, 1966. The subjects for the essays are as follows: (1) mechanisms of morphogenesis; (2) the pattern of sub-nuclear particles; (3) microcircuitry; (4) chemicals in agriculture; (5) the cell surface; (6) recent advances in thermochemistry. The essays, which must be in English and typewritten, should not exceed 4,000 words in length, and only one entry is permitted from each competitor. All entries should be addressed to: the Deputy Secretary, British Association for the Advancement of Science, 3 Sanctuary Buildings, Great Smith Street, London, S.W.1, and the envelope should be clearly marked '*Endeavour* Prize Essay'. The latest date for receipt of entries is June 1, 1966. The essays must be submitted without signature, and the competitor's full name and

address and date of birth should be enclosed in a sealed covering letter attached to the essay and addressed to the Deputy Secretary of the British Association.

The Mathematics of Control Systems

The second residential conference of the Institute of Mathematics and its Applications on "The Mathematics of Control Systems" will be held at Sunderland Technical College during April 3-6. The following lectures have also been arranged: "Non-linear Hydrodynamic Stability" by Prof. P. H. Roberts (Constantine Technical College, Middlesbrough, on February 21); "Reciprocity Theorems in Applied Mathematics" by Prof. G. J. Kynch (Birmingham College of Advanced Technology, on February 22); "Application of Mathematics to Problems arising in the Electrical Manufacturing Industry" by Mr. N. Kerruish (University of Leeds, on February 22); "Mathematics applied to the Large-scale Dynamics of the Atmosphere" by Mr. J. S. Sawyer (University of Strathclyde, on February 24); "Mathematics in Electrical Engineering" by Mr. N. Kerruish (Birmingham College of Advanced Technology, on March 2). Further information can be obtained from the Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex.

University and College News: Belfast

Dr. D. J. Bradley, reader in physics at Royal Holloway College, London, has been appointed to the chair of physics. The following appointments have also been made: *Readerships:* Dr. R. Common (geography); Dr. M. F. Grundon (organic chemistry); Dr. A. P. Roberts (engineering mathematics); Dr. F. J. Smith (applied mathematics); *Senior Lectureships:* Dr. R. M. Hobson (physics); Dr. D. McCloy (mechanical engineering); Mr. N. Stephens (geography); Mr. B. C. S. Wilson (archaeology).

The College of Advanced Technology, Birmingham

Dr. F. M. Page has been appointed professor of chemistry.

London

Dr. B. R. Coles, at present reader in physics at the Imperial College of Science and Technology, has been appointed to the chair of solid-state physics tenable at that College, from October 1.

Southampton

Dr. I. R. Beattie has been appointed to the chair of inorganic chemistry. Dr. J. M. Nightingale has been appointed to the chair of control engineering. Mr. R. A. Farrar has been appointed lecturer in mechanical engineering.

Announcements

Dr. M. A. Tuve, director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, has been appointed home secretary of the United States National Academy of Sciences, in succession to the late Dr. H. L. Dryden.

Dr. L. Schiff, executive head of the Department of Physics at Stanford University, has been awarded the 1966 Oersted Medal by the American Association of Physics Teachers, for notable contributions to the teaching of physics.

The address of the Plant Variety Rights Office is now Murray House, Vandon Street, London, S.W.1.

The title of the Fruit and Vegetable Canning and Quick Freezing Research Association is now the Fruit and Vegetable Preservation Research Association.

A symposium on "The Place of the Chemist in Industry", organized by the Royal Institute of Chemistry, will be held at the Oxford College of Technology on March 3. Further information can be obtained from Mr. W. Sabel, Oxford College of Technology, Headington Road, Oxford.

A symposium on "Chemistry and Rheology of Water Soluble Gums and Colloids", arranged jointly by the Colloid and Surface Chemistry Group of the Society of Chemical Industry and the British Society of Rheology, will be held at the School of Pharmacy, University of London, on March 28. Further information can be obtained from Mr. B. Warburton, Department of Pharmaceutics, School of Pharmacy, 29–39 Brunswick Square, London, W.C.1.

A working conference on inter-personal and inter-group relations entitled "Learning and Leadership", arranged by the Department of Adult Education of the University of Leicester in collaboration with the Tavistock Institute of Human Relations, will be held in the University of Leicester during March 25–April 7. Further information can be obtained from Miss D. J. Bostock, Tavistock Institute of Human Relations, 3 Devonshire Street, London, W.1.

Corrigendum. In the article entitled "Isotopic Ages of Minerals from the Pre-Cambrian Complex of the Malverns", by Dr. R. St. J. Lambert and D. C. Rex (*Nature*, 209, 605; 1966), the second sentence of paragraph three, p. 606, line 14, should read "A *Callavia* fauna . . .".

REVISING THE LAW OF PATENT

THE Patents Liaison Group was originally constituted in accordance with proposals made by Mr. R. Maudling, then President of the Board of Trade, in June 1961, to formulate views on the proposals of the Common Market countries with regard to a common patent system. The Group, at his further request, also advised the Minister on a draft of a Convention on unification of points of patent law proposed under the aegis of the Council of Europe and signed by the United Kingdom and other countries at Strasbourg on November 27, 1963. The Group was reconvened to consider the Convention and to report on those changes in the Patent Act, 1949, which would be involved in the ratification of the Convention by the United Kingdom. For this purpose, the Group, of which Mr. G. W. Tookey was chairman, was enlarged by representatives of the General Council of the Bar and the Law Society, in addition to those from the International Association for the Protection of Industrial Property (British Group), Association of British Chambers of Commerce, Chartered Institute of Patent Agents, Federation of British Industries, National Association of British Manufacturers, Trade Marks, Patents and Designs Federation, and the British National Committee of the International Chamber of Commerce who were originally included.

The report now presented to the President of the Board of Trade* points out that the Group's task was not to translate the provisions of the Convention into a United Kingdom statute. Instead, it was to undertake the complicated business of amending the existing Statute so as to remove parts which are inconsistent with the Convention and to insert in their place new provisions which conform to the requirements of the Convention and are couched in language which fits the general pattern of the Statute and is not ambiguous. The amendments should also make clear which precedents are applicable for the future and which are not. Much case law has been built up from the days of the Statute of Monopolies in 1623, and the definition of 'invention' is still based on the language of that early Statute. This Statute—it has been the subject of much judicial interpretation—requires alteration in certain respects.

The Group's recommendations are collected under four general headings, and those of major scientific interest are to be found under the first and third of these, relating to the novelty and inventive step and to patentable inventions, respectively. In the Convention an invention is stated to be new if it does not form part of the state of the art. This is defined as comprising "everything made available to the public by means of a written or oral description, by use or in any other way, before the date of the patent application or of a foreign application, the priority of which is validly claimed". Some extensive revision of the Patents Act, 1949, will be required to fulfil the obligations on this subject resulting from the Convention. The limitations of place and time in United Kingdom law must give way to the concept of absolute novelty and the law must be revised so that an invention is not regarded as new if in any way it has been made available to the public in any part of the world before the priority date of the patent application for the invention, or is obvious having regard to what has thus been made available to the public.

The group recommends that Section 32 (1) (*e*) and (*f*) of the Patents Act should be amended to read: "(*e*) that the invention, so far as claimed in any claim of the complete specification, already formed part of the state of the art as it existed before the priority date of the claim; (*f*) that the invention, so far as claimed in any claim of the complete specification, was obvious and did not involve any inventive step having regard to the state of the art as it existed before the priority date of the claim".

Further, the definition in Section 101 of the Act should include the following definition of the 'state of the art': "'State of the art' means all matter available to the public in the United Kingdom or elsewhere by means of a written or oral description, by use, or in any other way, so that persons skilled in the art are or can become acquainted with such matter."

It will be necessary to revise Section 7 of the Act so as to remove the provisions which limit the official search to United Kingdom patent applications dated within 50 years of the filing date; to delete the Sections relating to secret use; and to abolish the concepts of "invention of importation" and of the communicated inventions. Section 15 will also have to be revised so as to permit reference to any document published in the United Kingdom or elsewhere. Further amendment will be necessary to the Section protecting inventions displayed at an exhibition certified by the Board of Trade or described in papers read before learned societies, and the Section protecting inventions communicated under international agreements will have to be deleted.

With regard to patentable inventions, the Group considers that there is nothing in the Strasbourg Convention which would prevent the United Kingdom from formulating a new definition of invention. However, none of the proposals which it examined was free from difficulties, and the Group is satisfied that it is preferable not to frame a definition. The field covered by science and technology is already extremely wide, and, with the progress of time, the boundary of patentable subject-matter will inevitably increase. The Group considers it wiser not to seek to put a limit on what should be regarded as an invention and recommends that the new Act should not define 'invention' with any greater particularity than is necessary to conform to the Convention. Deletion of the existing definition and its replacement by wording to the effect that patents may be granted for inventions which can be made or used in any kind of industry, including agriculture, will lead to some uncertainty until the Courts have established some case law, but the Group was convinced that this flexible course was preferable to a restrictive one.

To some extent, the area of uncertainty can be narrowed by inserting in the Act a short list of exceptions. Two such exceptions are stipulated in the Convention itself: inventions contrary to *ordre publique* or morality and inventions in respect of plant or animal varieties. These the Group recommends should be specifically excluded: exclusion of plant or animal varieties from patentability is necessary to avoid overlap with the Plant Varieties and Seeds Act, 1964. The Group doubts, however, whether a distinction can or should be drawn between processes which are 'essentially biological' and those which are not, bearing in mind that any process for treating plants or animals which utilizes the natural functions of living matter will be more or less 'biological'. It recommends, therefore, that there should be no specific exclusion in respect of the plants or animals.

In addition to these exclusions, the Group recommends six other categories of exclusion, which might, in fact, be found by the Courts not to be 'inventions' within the meaning of the Act. These are: (i) methods of calculation: theoretical ideas and scientific principles; (ii)

* Board of Trade. *United Kingdom Patent Law: The Effects of the Strasbourg Convention of 1963.* (Report on legislative changes which would be involved in the proposed ratification by the United Kingdom of the Strasbourg Convention on the unification of certain points of substantive law on patents for invention by the Patents Liaison Group.) Pp. 18. (Cmnd 2835.) (London: H M S.O., 1965) 1*s* 6*d* net

business schemes (for example, methods of office management); (iii) commercial, financial and propaganda schemes; (iv) treatment of human beings; (v) designs or arrangements in which the novelty resides solely in appeal to the eye; (vi) designs or arrangements which serve only to convey information and in which the novelty resides solely in the information conveyed.

The Group recommends that adequate steps should be taken to enlighten agricultural interests as to the changes in the United Kingdom law which are contemplated and to explain the reasons for these changes.

The Group points out that the unification Convention does not completely solve the problem of how to resolve conflict with prior unpublished applications. Article 6 of the Convention broadly requires that parties of the Convention shall not allow double patenting. The present statutory provisions in the United Kingdom rest basically on the principle that double patenting is to be avoided, but the interpretation given to these provisions in recent years has produced serious difficulties. The Group agreed generally that a straightening out of United Kingdom law is necessary to bring some real sense into this subject quite apart from the requirements of the Convention. Generally, the Group is also agreed that a later patent should not be granted if it purports to prevent the working of the invention as claimed in an earlier patent in any manner in which a competent person would normally work it. Some suggested forms of wording for this 'prior claim' proposal are appended to the report. Nevertheless, the Group concludes that there should be no requirement that a patent granted on the earlier application should be granted, or valid if granted.

THE FUTURE OF NUCLEAR POWER

THE John Macrossen Lecture was given by Sir John Cockcroft in the same year as the third International Conference on Atomic Energy was held at Geneva. The Lecture is a very brief statement of the prospects of the economic development of nuclear power at that date, a subject very fully dealt with at Geneva. The capital costs per kW of electricity generated by the stations built by industry for the Central Electricity Generating Board will almost have halved in the 6 years between the completion of the 275-MW Berkeley station and the 1,180-MW Wylfa nuclear station, each of them containing two reactors. The fall is due in large part to the increased size of the unit; fuel costs have also fallen, but the overall cost of power by any calculation is still higher than that from coal-fired stations of the same dates.

The advanced type of gas-cooled reactor was expected in 1964 to cost less than a coal station of the same date, and within a year of the delivery of this Lecture the firm tender prices for the Dungeness *B* nuclear station showed that this was, in fact, the case, provided the station is built at the tender price.

In the United States similar dramatic falls in costs have been experienced with their water moderated reactors; and Canada's heavy-water reactor is expected to have very low fuel costs, although it will have a high capital cost.

These types of reactors, by the end of the century, would be using 100,000 tons of uranium per annum, on reasonable assumptions as to the rate of development of nuclear stations. To avoid a rise in the cost of raw materials, more of the uranium-238 must be used; the experimental fast reactor at Dounreay has operated well enough now to justify a design study for a 1,000-MW reactor to be ready for the late 1970's; this might herald a new generation of stations to use up the plutonium from the slow-neutron reactors and the fast reactor might breed 1·5 times the amount of fuel it uses.

Fusion reactions still remain as a possibility and as a hope for the future; stability of the confined plasma at low pressures has been achieved but not at high densities. It would be idle at present to predict whether these schemes will be successful. T. E. Allibone

NUMERICAL METHODS IN SUBSONIC FLUID DYNAMICS

A SYMPOSIUM on "Numerical Methods in Subsonic Fluid Dynamics" was held at the National Physical Laboratory during September 27–29, 1965, the local organization being shared jointly by the Aerodynamics and Mathematics Divisions. More than one hundred and thirty visitors from industry, universities, technical colleges and Government establishments, including several from Europe and the United States, participated in the programme, which was divided into four sessions, each consisting of two general survey lectures followed by three parallel discussion groups *A*, *B* and *C*. The subjects of the discussion groups were arranged so that *A* was a follow-up of the general lectures of the session, *B* was an independent subject introduced by a scheduled talk, and *C* was a more specialized subject determined by popular demand from the participants themselves.

The original initiative for the meeting came from the Aeronautical Research Council, which had some two years ago anticipated the need for a comprehensive examination of the role of the computer in fluid dynamics by setting up a Computer Panel. Quite early on, it became clear to the Panel that the full potentialities of the modern 'third generation' computer were not being adequately explored; consequently this symposium was arranged with the objects of elucidating some of the problems involved in the application of computers to fluid motions, and of stimulating interest in the exploration of new approaches to the subject which might be brought within the realms of possibility by the latest computing facilities.

The participants were welcomed by Dr. R. C. Pankhurst, representing the Acting Director of the Laboratory. Prof. B. Thwaites of Southampton University, chairman of the Computer Panel, then gave an introductory talk, in which he outlined the main problems facing the symposium. He suggested that scientists now needed to re-examine their motivations in research—were they interested mainly in mathematical analysis (which, in fluid dynamics, is very difficult) or in numerically expressed results? The answer might be different for the designer and for the 'pure' scientist. In either case, however, it was necessary to take into account the possibility of currently outstanding problems being solved, even within the next ten or twenty years, at the touch of a button; for this should surely influence the directions which work will take in the intervening period. Thus he emphasized the importance of directing the discussions towards what will be done in the future.

This was followed by a talk on "The Relevance of Numerical Analysis" by Prof. L. Fox of the University of Oxford. He concerned himself mainly with the finite-difference solution of the relevant types of partial differential equation, paying particular attention to the solu-

tion by iterative methods of the associated difference equations. He also discussed the problem of truncation error, in particular the treatment of singularities, but emphasized the outstanding gap remaining between the practical problems one wanted to solve and the problems for which rigorous error estimates could be given. Questions of stability arise with initial-value problems, and these he discussed with reference to parabolic equations. Among other topics mentioned were the effect of non-linearities and problems with free boundaries.

The participants then split up into the three parallel discussion groups, *A*, *B* and *C*. In this session, group *A* was on "Numerical Analysis" and was chaired by Dr. E. T. Goodwin (National Physical Laboratory); the discussion ranged over a wide variety of questions raised by Prof. Fox's talk. Group *B* was concerned with "Meteorological Forecasting by Computer" and was chaired by Prof. P. A. Sheppard (Imperial College of Science and Technology); it was introduced by Mr. E. Knighting of the Meteorological Office. Mr. Knighting outlined the three main computing tasks involved: selection of reliable data from those received from the international recording stations, conversion of this for use on a regular square grid, and, finally, integration of the relevant equations. With regard to the latter he discussed methods of integrating simple vorticity equations with the emphasis on simplicity and time-saving since forecasting must be carried out in real time. A lively and worth-while discussion followed.

In the other parallel discussion group (*C*) a relatively small number had assembled to discuss "Magnetohydrodynamics" under the chairmanship of Mr. D. S. Butler (University of Strathclyde). Several problems were mentioned that clearly needed the use of a large computer, but it appeared that in some cases these were being tackled without sufficient consideration of the physical concepts involved; in particular, problems were being tackled which seemed to be far too complex to offer any hope for a successful conclusion, and it was remarked that the computer seemed to be inducing people to run away from reality. A lively discussion followed on how computers could best be used, and the view that it would be profitable at this stage to try to compute simple 'component flows' first was widely supported.

The morning session of the following day began with a lecture by Mr. A. M. O. Smith of Douglas Aircraft on "Integral Equation Methods for Potential Problems", in which he demonstrated that, with the advent of large computers, these methods, based on source distributions over the surface of the body, had become a practical means of computation for general non-lifting three-dimensional problems. The numerical procedure was basically quite simple and consisted in reducing the problem to an algebraic one by dividing the body up into a large number of small elements and assuming the source density constant over each element. The most complicated problem attempted to date was the determination of the flow over a swept wing having two jet-engine nacelles complete with pylons and internal ducts. Though this problem was really beyond the capacity of the present computing equipment, the calculations and test data were in better than merely qualitative agreement.

Mr. J. A. Bagley of the Royal Aircraft Establishment followed with a survey lecture on "Subsonic Wing Design". He traced the development of the traditional methods of wing design and discussed the difficulties which have to be faced in improving them. He made it abundantly clear that it will be quite insufficient merely to improve methods of calculating the inviscid incompressible flow, but pointed out that even for the much simpler two-dimensional case the problem of calculating the viscous compressible flow seemed to be some way from being solved.

In the following discussion groups, *A* was concerned with "Inviscid Flow" (chairman: Prof. G. N. Ward, University of Sussex), *B* with "Programming Languages and Programme Interchange" (chairman: Prof. S. Gill, Imperial College), and *C* with "Hydrodynamic Stability" (chairman: Mr. M. Gaster, National Physical Laboratory). In the *A* group the topics discussed were centred around wing theory; in particular there were discussions on recent methods for lifting surfaces, and on the non-convergence of the circulation when the displacement effect of the boundary-layer is taken into account. Mr. P. M. Woodward of the Royal Radar Establishment introduced discussion *B* with a brief historical review of programming and an analysis of the role of the specialist systems-programmer. He emphasized the need for mathematicians and numerical analysts to become literate in Algol. A lively discussion ensued which tended to underline the difficulties of thinking in terms of using a nebulous machine to which one might have access in the future when results were needed to-morrow. In group *C* the main topic discussed was the application of modern computer techniques for eigenvalue problems to linear stability theory, particularly in regard to boundary-layer stability.

The first half of the afternoon session consisted of a double lecture on "Boundary-layer Problems" shared by Prof. K. Stewartson of University College, London, and Dr. K. W. Mangler of the Royal Aircraft Establishment. This was confined solely to laminar boundary-layers, for which a determinate system of equations exists. Prof. Stewartson gave detailed consideration to the nature of the initial-/boundary-value problems which arise for these equations and to the simpler numerical techniques for their solution. He observed that the first real difficulty arises near separation, where in general the wall friction vanishes with a singularity, and mentioned techniques which could deal satisfactorily with this. He emphasized the importance of setting oneself a well-posed problem for which existence or uniqueness could be proved, and, looking to the future, briefly discussed this question with regard to the treatment of backflow on the basis of the boundary-layer equations. Dr. Mangler carried the story further, dealing with the extra complications encountered with compressible flow and quasi-three-dimensional flow on a conical surface. He also described in greater detail the various methods that had been programmed for specific problems and discussed a technique for adjusting the external pressure distribution so as to obtain a regular solution at separation.

The subjects for the discussion groups after tea were as follows: *A*—"Boundary-layer Problems" (chairman, Prof. L. Howarth, University of Bristol; *B*—"Free-boundary Problems" (chairman, Prof. M. B. Glauert, University of East Anglia); *C*—"Numerical Analysis" (chairman, Mr. C. W. Clenshaw, National Physical Laboratory). In group *A* Mr. G. S. Raetz (Northrop Aircraft) gave an account of his finite-difference method for solving the three-dimensional boundary-layer equations. This was followed by a general discussion of points arising out of the previous lecture. Mr. J. H. B. Smith of the Royal Aircraft Establishment introduced discussion *B*. After indicating the variety of situations in which free boundaries occur (such as at the surfaces of oceans, or of air bubbles rising through water or of the oil in journal bearings, in the design of wing shapes for a given pressure distribution, at the trailing vortex sheet behind a wing, at shock waves in locally supersonic flow, and at the surface of a sail distorted by wind forces), he drew a distinction between those problems which could be transformed into or approximated by a fixed boundary problem before numerical treatment and those which could not. He then described briefly a number of proper free-boundary problems and discussed in detail one in particular which had recently been solved successfully, namely, the determination of the strength and shape of spiral vortex sheets in a model of a flow with separation from a highly swept leading edge. In group *C* the discussion on "Numerical Analysis" was continued; more detailed consideration

was given to the treatment of singularities, and a general debate ensued on the kind of problems that numerical analysts ought to be examining.

The final session on the morning of September 29 was devoted largely to what must be the most challenging problem to fluid dynamicists, namely, the solution of the full Navier–Stokes equations. In the first lecture, Dr. S. C. R. Dennis of the University of Sheffield surveyed the progress to date in the field of steady flow, and discussed in considerable detail the difficulties that arise in tackling the classical external problem of two-dimensional flow past a circular cylinder. In particular, he considered suggestions that might overcome the major difficulty of the flow in the wake, which is especially troublesome at higher Reynolds numbers.

In the next lecture, on "Unsteady Flow", Dr. J. E. Fromm of the Los Alamos Scientific Laboratory demonstrated the feasibility of using a large digital computer to simulate the complex asymmetric fluid motions which really do occur in practical flow régimes, where the steady flow is unstable. He first gave a description of a finite difference technique for obtaining solutions of the two-dimensional unsteady Navier–Stokes equations which had been developed with due regard for stability and conservation properties. He then showed a series of impressive ciné films of the computer output for several flow problems. In order to make best use of the finite computer storage, only restricted flow fields were considered, namely, those between parallel plates. In the first problem the plates were moved so as to accelerate the fluid past a rectangular body; in the second the same configuration was considered, but the uncoupled temperature equation was solved as well, so as to simulate forced heat convection from the body. In the third problem, the Benard problem of thermal convection between fixed plates was considered; here, of course, the coupling between the temperature and momentum equations had to be taken into account. The filmed computer output showed the development in time of the streak-line patterns, the general features of which resembled the corresponding patterns produced in experiments to a remarkable degree. Shown also were the changing vorticity line patterns (or for the convection problems isotherm patterns). It should be noted that if the data given were exactly symmetric, the symmetry was preserved in the solutions. The asymmetry had to be stimulated by introducing small perturbations; these were damped out for small Reynolds numbers, but amplified into typical eddying motions for larger Reynolds numbers. In the discussion group *A* that followed (chaired by Prof. I. Proudman, University of Essex), it was pointed out that external flow problems were substantially more difficult to deal with numerically than internal ones, and Dr. Dennis suggested that a combination with analytical treatment of the far field might be the answer; however, it would be very interesting to see Dr. Fromm's method applied directly to external flow problems. Another restriction that had been imposed because of limited storage capacity was a periodic boundary condition in the general flow direction; it would be of considerable interest to remove this so that any ultimate quasi-steady patterns for large times could be studied.

The other two discussion groups on this last morning were: *B*, "Internal Aerodynamics" (chairman, Prof. J. H. Horlock, University of Liverpool) and *C*, "Turbulent Boundary-layers" (chairman, Prof. A. D. Young, Queen Mary College). Mr. R. Hetherington of Rolls-Royce, Ltd., gave an introductory talk in discussion group *B*, in which he discussed the two main two-dimensional problems that were used to model the essentially three-dimensional process of flow through the complex of rotating and stationary blades that comprise a turbomachine. These are concerned mainly with curved axial flow and cascade flow, respectively. Presently available methods were briefly described and the extent to which computers were being used was surveyed. Although new methods were clearly needed to deal with the non-linear compressible and viscous effects, it was concluded that much could still be gained by developing existing methods with the aid of the modern computer.

The subject of turbulent boundary layers is, of course, of the utmost practical importance, but, up to the present, methods for calculating them have been developed on a purely empirical basis. Discussion group *C* did, however, indicate that some substantial progress towards removing the empiricism from the direct relationship between shear stress and mean velocity profile to a less critical level is at last being made through analysis of the turbulent energy equation. This method leads (in two-dimensional flow) to a third-order hyperbolic system of partial differential equations, for which a characteristics method has been devised for solution on the computer. The computer can also be used to develop the traditional approach by exploring quickly and accurately the consequences of the various empirical assumptions regarding the relationship between shear stress and mean velocity profile. Here the differential equations are of similar type to the laminar boundary-layer equations, so with appropriate modifications the numerical techniques developed for the latter may be carried over.

The attention of the Computer Panel had recently been brought to work done at the National Physical Laboratory on the optimization of hull form parameters based on a statistical analysis of results from model tests of trawlers. The possibility of applying similar techniques to aircraft was thought worthy of investigation, so an additional discussion group was arranged to consider this after lunch on the last day. Mr. J. G. Hayes of the National Physical Laboratory described the technique in an introductory talk based on his paper on "Optimum Hull Form Parameters" read at the symposium on "Numerical Methods Applied to Shipbuilding" held at Bergen in 1963. Mr. D. J. Doust of the National Physical Laboratory added details of the significant improvements obtained in trawler design, and a short discussion followed under the chairmanship of Mr. J. G. L. Michel (National Physical Laboratory).

No proceedings are being published, but some copies of the programme and abstracts are still available and may be obtained from Mr. P. G. Williams, Mathematics Division, National Physical Laboratory, Teddington, Middlesex, under reference *Ma.* 8/35/02.

P. G. Williams

BIOLOGICAL SCIENCES IN THE FUTURE UNIVERSITY OF BATH

On October 14, 1965, the first and preliminary-phase building of the future University of Bath was officially opened by the Mayor of Bath. Designed by the University architects, Robert Matthew, Johnson-Marshall and Partners, this building occupies a corner of the 197-acre site set aside by the City of Bath for the development of the new University. Constructed on the C.L.A.S.P. system, the structure was virtually completed in less than ten months, between the turning of the first sod in September 1964 to the handing over by the contractors in July 1965.

The two-storey structure forms a quadrangle, surrounding a central paved courtyard, the inner sides consisting mainly of staff offices and workrooms and the outer sides containing teaching laboratories, lecture and seminar rooms. Included in the specialist accommodation are

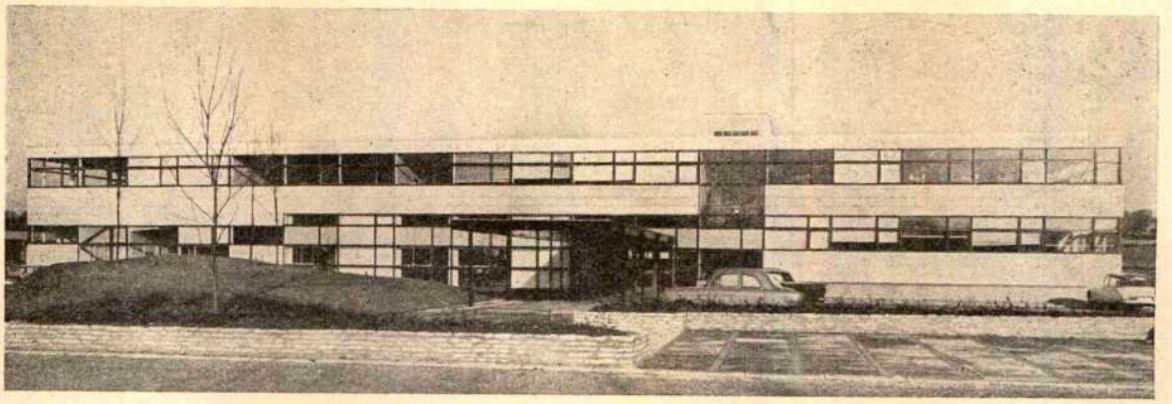

Fig. 1. The first and preliminary-phase building of the future University of Bath

laboratories for biochemistry, microbiology, crop protection, horticultural science, plant and animal physiology, electron microscopy and a variety of instrumental techniques. In addition to housing the School of Biological Sciences, about one-quarter of the total teaching space of 20,000 sq. ft. is being used by the School of Humanities and Social Sciences. The building also provides the essential ancillary accommodation, including library, refectory and staff and student common rooms. The total biological accommodation provides for an annual intake of about sixty students, giving a total for the four years of the first degree sandwich courses of about 240, divided almost equally between the existing course in applied biology and new first degree courses in applied biochemistry and horticulture starting in the present session. The development plan for the University provides for a further instalment of about 12,000 sq. ft. of biology accommodation in the next phase of the building programme, scheduled for completion in 1967.

The history of applied biology in the University of Bath may be traced back to 1956 when the Bristol College of Technology was designated as one of the original Colleges of Advanced Technology. At that time, in the newly-styled Bristol College of Science and Technology a four-year sandwich course in applied biology was started at the college site in Ashley Down, Bristol, under the aegis of the National Council for Technological Awards and leading to the Diploma in Technology. This course, which was designed to train biologists for employment in industry, research and development, provided for three years of broadly based biological training, followed by a fourth-year specialist option in either pharmacology, microbiology, plant physiology, plant pathology or entomology. Each year of the course consisted of about equal periods in college and in industrial or research establishments. The course has since been modified in the light of experience, by an extension of the period of specialized study to two years, with the fourth year spent entirely in college, and by the combination of entomology and plant pathology in a combined course in crop protection.

The establishment of a School of Biological Sciences coincided with the opening of the new building for the autumn term. The title formally expresses the intention to preserve and extend the integration of biological education and research in those fields of biology with which the School is concerned. Both for educational reasons, and to preserve the greatest possible flexibility in students' choice of their final specialist training, it is hoped that this integration may eventually be extended by providing a common first-year course in the groundwork of biology to be followed by all new entrants to the School. For administrative convenience the teaching and research staff are divided into working groups, corresponding so far as possible with the main areas of interest within the School. Initially these groups are biochemistry, microbiology, comparative physiology, horticulture and plant physiology. The present teaching staff numbers twenty-two and there are nine research students. The head of the School and first professor of biology is Dr. L. Broadbent, at present honorary secretary of the Institute of Biology and formerly head of the Plant Pathology Division of the Glasshouse Crops Research Institute. M. W. HARDISTY

POLYMERIZATION IN A GLOW DISCHARGE

By DR. T. WILLIAMS and M. W. HAYES
British Iron and Steel Research Association, London, S.W.1

GLOW-DISCHARGE polymerization has been known for many years; for example, Linder and Davies[1] described the gases and solids formed by some hydrocarbon vapours in a glow discharge. In a more recent article, Brick and Knox[2] have described the major features and variables associated with this process. Other articles have been published describing the chemical, physical[3] and electrical[4] properties of glow-discharge polymers.

In glow-discharge polymerization, organic vapours at a pressure of about 1–5 torr are introduced into a chamber containing two parallel electrodes. An a.c. voltage is applied across the electrodes so as to initiate, and then sustain, a uniform glow discharge in the intervening space. High-energy ions and electrons are produced in the glow and these bombard both the electrode surfaces and the molecules in the gas phase. These interactions initiate complex chemical reactions which result in the formation of thin (up to about 5μ) uniform and continuous coatings on the electrode surfaces.

A schematic diagram of the apparatus used in the glow discharge polymerization experiments is shown in Fig. 1. The electrodes were made of mild steel (approximately 5 cm by 10 cm) and held in position by non-conductng supports. They were normally placed about 2 cm apart. The apparatus also had provisions for cooling one electrode down to a minimum temperature of −30° C.

The electrical equipment consisted of an oscillator and 1 kW audio amplifier. With frequencies of about 10 kc/s the glow was initiated at about 800 V and sustained at approximately 400 V. Most of the present work was

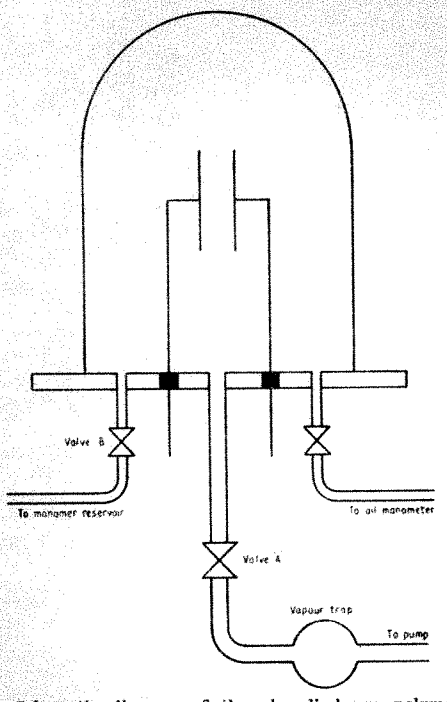

Fig. 1. Schematic diagram of the glow-discharge polymerization apparatus

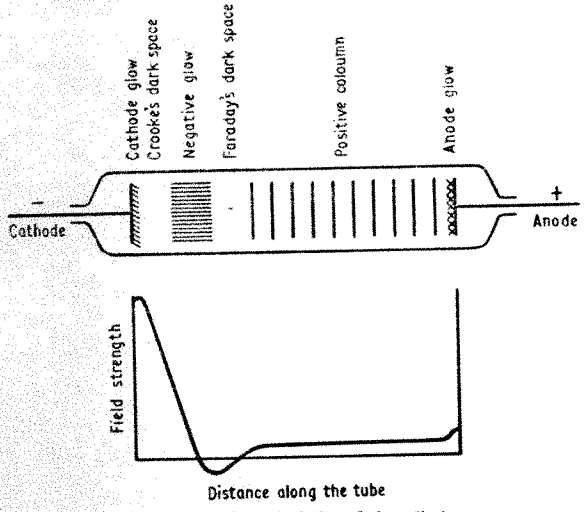

Fig. 2. Some characteristics of glow discharge

carried out with discharge currents varying between 1 and 5 m.amp/cm^2.

Two experimental procedures were adopted: in the first the bell-jar was pumped down and purged continuously with monomer vapour for about 15 min. Valve *A* was then closed and monomer vapour allowed to build up to the required pressure. Finally, valve *B* was closed. In the second procedure—where there was a continuous flow of vapour through the apparatus—valves *A* and *B* were adjusted manually to give the desired pressure.

With an a.c. field, the two electrodes were experimentally indistinguishable. The weight of polymer on each electrode was determined and an average of the two readings recorded. Film thickness was calculated from the weight, area of electrode and the density of the polymer; the latter was taken as 1·0. Results obtained in this manner compared well with those calculated from film capacity measurements, where the dielectric constant was taken as 3·0. All results were reproducible to within ± 5 per cent.

Some essential features of glow discharge. The essential features of a glow discharge have been described elsewhere[2,5]. A diagram of a d.c. discharge conducted in a gas at a pressure of about 1–5 torr is shown in Fig. 2. Electrons originating near the cathode experience the electrostatic repulsion of the cathode and move into the Crooke's dark space which is the region of the greatest potential drop. In this region the electrons are accelerated to their maximum energy, which depends on the potential drop and the pressure of the discharge. The electrons emerge from the Crooke's dark space and enter the negative glow, where they bombard the gas molecules, forming a wide range of species which include ions and activated molecules. Positive ions formed in the negative glow move into the Crooke's dark space and are accelerated by the high field in this region; these ions then strike the cathode, liberating more electrons which follow the sequence already described.

The electrons leaving the negative glow have lost most of their energy in collisions with gas molecules. What happens to the electrons afterwards is not important for this discussion, and the rest of the discharge may be regarded as diffusion of electrons towards the anode, where they are neutralized.

When alternating current is used instead of direct current, then, again for the purpose of this discussion, each electrode may be regarded as acting alternately as the cathode.

The description already given is general for all glow discharge. Most of the work from which the discharge mechanism was established was carried out with such gases as hydrogen, nitrogen and the noble gases. In the present investigations, all the work is concerned with organic vapours which react chemically in the presence of a glow forming polymer coatings on the electrode surfaces. Some of the complications introduced by such a behaviour are discussed below.

The equivalent circuit for the glow-discharge polymerization process. Fig. 3 represents an a.c. glow discharge occurring in an organic vapour. Fig. 4*a* is a simplified equivalent circuit for the process after the formation of polymer films on the electrode surfaces. Let:

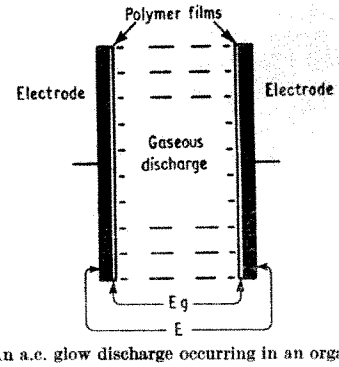

Fig. 3. An a.c. glow discharge occurring in an organic vapour

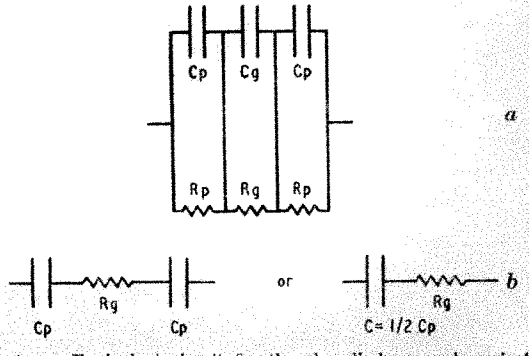

Fig. 4. *a*, Equivalent circuit for the glow-discharge polymerization process. *b*, Simplified equivalent circuit for the glow-discharge polymerization process

R_p be the resistance of the polymer film in ohms (Ω);
C_p, the capacitance of the polymer film in farads (F);
R_g, the resistance of the gas in Ω;
C_g, the capacitance of the gas in F;
X_p, the reactance of the polymer film in Ω;
X_g, the reactance of the gas in Ω.

With frequencies at least up to 10 kc/s the circuit shown in Fig. 4*a* may be further simplified (see Fig. 4*b*) because for a thin polymer film the resistance $R_p \gg$ reactance X_p and also for the gas, reactance $X_g \gg$ resistance R_g.

Since the films deposited on the two electrodes are identical in thickness and properties, the effective capacitance of the circuit is:

$$C = 1/2\ C_p \quad (1)$$

The reactance of each polymer film is:

$$X_p = 1/\omega C_p \quad (2)$$

where $\omega = 2\pi f$ and f is the frequency. The effective reactance of the circuit is:

$$X = 1/\omega C \quad (3)$$

Now the capacitance of a polymer film is given by:

$$C_p = \varepsilon_0 \varepsilon_r\ A/d \quad (4)$$

where ε_0 is the permittivity of vacuum ($8{\cdot}854 \times 10^{-12}$ F/m); ε_r, the dielectric constant (or relative permittivity) of the polymer; A, the area in square metres; and d, the film thickness in metres. The impedance of the circuit (Z) is expressed by equation (5) (where j is $\sqrt{-1}$):

$$Z = R_g + 1/j\omega C \quad (5)$$

The magnitude of Z can be calculated from the expression:

$$|Z| = \sqrt{R^2_g + (1/\omega C)^2} \quad (6)$$

The voltage drop across each polymer film, E_p, is given by:

$$E_p = I\ X_p \quad (7)$$

where I is the current in the circuit.

The voltage drop across the whole circuit may be calculated from the following equation:

$$E = I\ |Z| \quad (8)$$

$$= I\ \sqrt{R^2_g + (1/C\omega)^2} \quad (9)$$

If the field strength across a polymer film exceeds the dielectric strength of the polymer, then electrical breakdown of the film occurs. With a d.c. discharge ω is zero, and therefore from equation (7) the voltage drop across any film covering the electrode must be infinite. In practice this means that no continuous films can be formed with a d.c. discharge.

According to equations (2), (4) and (7) the voltage across the film depends on the current density and frequency. At a given frequency continuous coatings are formed when the current density is such that the voltage across the films is not greater than the electrical breakdown of the polymer. Table 1 shows the variation of voltage across a film with current density and frequency. In the megacycle range the field strength across the film is low compared with breakdown voltage of polymers even at very high current densities ($\sim$ 50 m.amp/cm²).

The effect of film thickness on the discharge voltage is very small under normal operating conditions. If the electrode area is taken as 1 cm², current as 10 m.amp, frequency as 10 kc/s and the dielectric constant of the polymer as 3·0, then the rise in discharge voltage due to the build up of a micron film on each electrode may be calculated from equations (4) and (9).

Table 1

Frequency	Current (m.amp/cm²)	Field strength across film (V/μ)
10 kc/s	1·0	6·0
10 kc/s	5·0	30 0
10 kc/s	10 0	60·0
100 kc/s	5·0	3·0
1 Mc/s	5·0	0·3
1 Mc/s	50·0	3·0
10 Mc/s	50·0	0·3

Initially, when there is no polymer on the electrode the voltage across the gas is equal to the voltage across the whole discharge, that is:

$$E_g = E \text{ at } d = 0$$

If $E = E_g = 500$ V, then the resistance of the gas is 50,000 Ω.

The effective capacitance of the discharge calculated from equations (3) and (4) is $1{\cdot}3 \times 10^{-9}$ F and the total reactance of the discharge is:

$$X = 1/\omega C$$
$$= 12{,}000\ \Omega.$$

Substituting these figures in equation (9) the voltage across the discharge, when the electrodes are coated with a 1μ film, may be calculated; this voltage is 514, which is only a 2·8 per cent increase on the initial voltage when the electrodes were uncoated. At 1 Mc/s the voltage change is negligible even up to film thickness of 10μ.

Clearly, if the voltage is kept constant there is very little change in current as the film thickness increases up to 1μ at 10 kc/s.
